September, 1869, she was seized with pain in the right side, and in April, 1870, two tumors were noticed by Drs. Sabine and Brown, occupying a central position, inclining towards the right inguinal region. They were hard to the touch, and the patient experienced pains of an expulsive character, with movements resembling those of a fœtus. The tumors were thought to be fibroid, and, by some, malignant, and the fluid, which soon after accumulated, was supposed to be in the peritoneal cavity. November 24, 1870, she was tapped, and four gallons of dark-green syrupy fluid were removed. January 15, 1871, she was tapped again. The fluid was similar in color, but thicker, and containing cheese-like flakes. The tappings were repeated on the 22d of February, the 28th of March, the 22d of April, and the 15th of May,—in all six times. After each tapping a large, solid tumor was detected occupying the right side. It was circumscribed, movable, and not tender on pressure. She always rallied after the tappings, excepting the last one. During the last month emaciation was rapid.

On examination, the patient was found to be larger than a woman at full period of pregnancy, although so recently tapped. She was much emaciated. The whole abdomen was elastic, and more or less fluctuating, but the fluctuation was most distinct throughout the upper portion. The only resonant point was over the left hypochondrium. No ridges or nodules could be distinctly detected, although considerable resistance to pressure could be felt over the lower part of the right side. The lower extremities were swollen, and the hypogastric region was œdematous. The uterus was elevated, and rather fixed in position. The pelvis was free.

Diagnosis.—Multilocular ovarian tumor. Ovariotomy was performed, the following gentlemen being present: Drs. W. K. Brown, D. E. Kissam, W. A. Kissam, H. S. Smith, G. K. Smith, T. Fleet Speir, E. N. Chapman, and J. E. Clark, all of Brooklyn, New York.

On examining the left ovary, a cyst as large as a filbert was found on its distal extremity, and freely incised.

The tumor was multilocular, consisted of the right ovary, and, with its contents, was estimated to weigh about fifty pounds.

Died on the eighth day, of pyæmia.

Dr. S. Fleet Speir examined the tumor after its removal, and reported as follows: "The tumor was found to be a simple ovarian cyst, containing a viscid, glairy, slightly opaque, and albuminous fluid. The envelope was thin in some parts, and in other places thick, and on its inner surface, near its connection with the ovarian structure, there were some hypertrophied villi. On microscopic examination, no evidence of malignant disease was discovered."

TRANSLATIONS.

THE ACTION OF COLD WATER UPON THE SPLEEN.

BY DR. R. M. BERTOLET.

PROF. FR. MOSLER gives, in *Virchow's Archives*, vol. lvii. (1873), Heft 1, the details of a very interesting series of experiments performed upon the lower animals to ascertain the action of cold water upon the contractility of the spleen. The results obtained prove conclusively that a decided contraction of the normal healthy spleen is brought about when cold water, either in the form of the douche or ice-bags, is applied directly to the exposed organ, or simply upon its integumentary coverings; that by the former method a more marked diminution of the volume, a more highly granular condition of the surface of the spleen, is obtained than when the skin is allowed to intervene. The granular condition of its surface, the firm consistence of its parenchyma, and the diminution of the organ, are more marked the longer the time of application. When the cold water is applied to the exposed organ, the appearances presented in it are similar to those observed after the use of large doses of quinine.

The practical upshot of these experiments lies in the fact that Prof. Mosler was led to make a number of most careful observations upon the therapeutic value of cold water in both acute and chronic splenic tumors, and that he finds it a valuable adjuvant to the internal administration of quinia or cinchonia in all such cases.

The beneficial effect of combining these two methods of treatment is conclusively shown in the clinical records of cases of intermittent fever, leukæmia, pseudo-leukæmia, etc., the enlarged spleen in every instance being sooner or later reduced in size.

The cold douche is applied to the region of the spleen twice daily, from 1½ to 2 minutes at each time. The possibility of also obtaining a mechanical effect by the cold douche has led the author to give it the preference to the simple cold compress or lumps of ice.

The results that Prof. Mosler has obtained from his observations and experiments may be thus summarized:

I. Direct contact of cold water upon the normal spleen produces a visible contraction of the organ.

II. A lesser degree of contraction is obtained in the normal spleen when the cold water is applied upon its integumentary coverings.

III. Also in the pathological splenic tumors, acute as well as chronic, the action of cold water is demonstrable in the diminution of their size immediately after its use.

IV. The febrile paroxysms of intermittent fever can be terminated by the cold douche when used one or two hours before the precise time of the expected attack.

V. The cold douche does not deserve the preference to quinine either in recent or protracted cases of intermittent fever.

VI. The curative action of the cold douche in intermittent fever is not complete. It does not always prevent a return, and leaves, also, as does quinine, a chronic splenic tumor.

VII. The splenic tumor of typhus is also diminished by the application of cold water.

VIII. A combination of the application of cold water upon the spleen, either in the form of cold baths, or ice-bags, or cold douches, and at the same time the exhibition of quinine, is preferable in the treatment of acute and chronic splenic tumors to the use of either of these means alone.

IX. In the treatment of chronic splenic tumors, the combination of the application of cold water upon the region of the spleen, with the administration of the much cheaper alkaloid cinchonia, is to be recommended.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 5, 1873.

EDITORIAL.

WOMEN IN HOSPITALS.

THE vexed question of woman in medicine—her present and future—is a rather warm one for a season so close to the dog-days, but we learn from the *London Lancet* that admission has been demanded by some of the advanced thinkers of Birmingham to all the advantages offered by the Medical School of Queen's College, and that, whilst the proposal has met with a favorable consideration from the teachers of the school, the students are opposed to it. The *Lancet* thinks that neither the parents of the young gentlemen nor the patients of the hospital have been consulted, and, after asserting that they ought to be, says:

"We wish to know whether the male patients of the Birmingham charities are prepared to have catheters passed, hydroceles tapped, or hernias manipulated by the hands of *female* students; for, unless they are, those ladies cannot properly learn their work. We quite agree with the writer we have already quoted when he says:

"'Female practitioners can never be of any use whatever to the public unless they go through exactly the same training, both mental and moral, as their male competitors; and, as in after-life they can never practise any department of the profession isolated from men, it is absurd that they should start and spend the most important part of their professional existence apart from them.'

"All this is perfectly true; but, so long as human nature is what it is, we do not believe decent men will willingly submit to surgical treatment at the hands of the opposite sex."

We ask, Why not? *Chacun à son gout.*

And so said a female medical student in a communication published in an issue of the *Lancet* subsequent to that from which the above quotation is taken; whereupon the editor of the *Lancet* replied:

"We regret to have to put our statement more forcibly and plainly than we did before, but the extreme ignorance or innocence of our correspondent demands it. Our view is that 'so long as (masculine) human nature is what it is,' we do not think male patients can be submitted to manipulative examination by female students without the risk of an involuntary manifestation of excitement which would be painful to both parties."

WE are glad to inform our readers that Professor Ferrier and Dr. Lauder-Brunton, of London, have promised to be regular contributors to our journal. In a letter to the editor, Dr. Brunton, speaking of Professor Ferrier, says, "He has obtained a grant from the Royal Society to pursue his researches on monkeys. Already his experiments on his simian cousins have been commenced, and the results are most satisfactory. He can make an animal follow his command by simply touching different parts of the brain by the electrode, and 'eyes right,' 'eyes left,' 'eyes open,' 'eyes shut,' 'mouth open,' 'mouth shut,' 'tongue out,' 'tongue in,' etc., follow as certainly as the machinery of a London penny steamer follows the commands, 'ease her,' 'stop her,' 'back her.'" It certainly looks squally for Professor Brown-Séquard's theory of the origin of brain-symptoms.

DR. TYLER SMITH, the eminent obstetrician, died suddenly, on the 3d ult., at Richmond, near London, from the effects of cerebral hemorrhage. He had been for some time ailing in health, and indications of Bright's disease of the kidneys and of arterial degeneration had been detected. Subcutaneous ecchymoses, and occasional attacks of severe epistaxis, preceded the apoplectic seizure, which was, however, apparently unexpected, as he was found insensible by the road-side and died in the Richmond Infirmary. His career as a philosophic thinker, an accomplished writer, and a successful practitioner was one of considerable activity and honorable achievement. He is known to the profession through his able monographs on parturition and its processes, and on the pathology and treatment of leucorrhœa, and also as the author of

what was, in its day, one of the best manuals of obstetrics in the language.

OUR editorial upon the use of ether in a recent number of the *Times* has called forth a letter from Dr. R. J. Levis, of the Pennsylvania Hospital, from which we make the following extract:

"I have repeatedly etherized very aged persons, and recognize no manifestations peculiar to them. One of the cases was that of Mrs. Hopkins, No. 545 North Sixth Street, etherized profoundly, at the age of *ninety-six*, and a perfectly successful operation of extraction of cataract performed.

"Another, a patient of the late Dr. C. H. Taylor, of this city, aged *ninety-two*, was etherized to complete anæsthesia and muscular relaxation, and I performed the operation for strangulated hernia, which was followed by recovery."

H. NOAH MARTIN, Professor of Practice of Medicine in Hahnemann Medical College of Philadelphia, has made the discovery that for gentlemen of color no medicine is like unto nux vomica. "Where no indications for any special medicine can be found," he says, "give nux vomica to colored people with reasonable assurance of benefit." Who can sound the depths of human fatuity?

IN a letter to a gentleman living in this city, Professor Alfred S. Taylor, of London, says, "With regard to the Van Ness case, I can see nothing to prove that the symptoms were caused by strychnia. In a new edition of my work on Poisons, which I hope to prepare, I shall examine more minutely these two cases [two Wharton trials.—*Ed. M. T.*], which are very important in relation to medical evidence."

OWING to the approach of the epidemic, we shall devote our next number entirely to cholera.

It will contain a lecture upon the subject by Prof. Stillé, an original article on the value of sulphuric acid as a prophylactic by Dr. R. G. Curtin, and a leader upon disinfectants by Dr. H. C. Wood, Jr., besides a sketch of the present epidemic, and other matters of interest.

WE have to thank Dr. Caldwell for a copy of the constitution and by-laws of the Maryland Epidemiological Association, a recently formed and apparently live society of Baltimore.

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

Professor Sharpey and Professor Owen—The Royal Society—Dr. Radcliffe's Croonian Lectures—The Emperor Napoleon's Sleeve-links—Sir Henry Thompson's Fee—The Contagious Diseases Acts—The Results of their Operation—Parliamentary Division in their Favor—Compulsory Registration of Births and Deaths—New Books—Haughton and Helmholtz on Teleology—Practical Physiology.

I HAVE not before me a copy of my last letter, and do not very clearly remember to what date my chronicle of recent events has been brought. The most recent of minor events are the promotion of Professor Owen to the Commandership of the Bath, the operation on Professor Sharpey, our dean of physiologists, for cataract, and the presentation of the Emperor Napoleon III.'s sleeve-links, set in a gold box, to Sir William Gull, by the Empress Eugenie. Men of science rarely receive British decorations, and, indeed, many of our highest savans have followed the example of Faraday in refusing them. There is no special order of merit for eminence in science and literature; and when knighthoods and baronetcies are conferred the savant commonly finds himself on his way to Windsor or Osborne on the same train with aldermen, common-councilmen, provincial mayors, and successful traders, and the honor is considered equivocal. The true title of scientific honor here is F.R.S., and the fellowship of the Royal Society is the most creditable title of nobility which can be attached to a man of science.

At the last election into the Royal Society very few medical men were admitted, and those chiefly on other than purely medical grounds. Sir Alexander Armstrong was admitted as head of the Naval Medical Department, Dr. Roylston Pigott as a greatly accomplished mathematician and microscopist, and Dr. Aitken, Dr. Paget, and Dr. Beddie, as possessing official or scientific claims apart from merit as practitioners. Dr. C. B. Radcliffe, well known in both hemispheres as an eminent physician and physiological inquirer into the electrical conditions of nervous and muscular action, has been long a candidate, and hoped this year for admission, but vainly. Ingenious as are his theories of muscular contraction, they are opposed to the conclusions of all other electro-physiologists, and are looked upon as illogical and wholly unsound. But his fate was sealed by his recent Croonian Lectures at the Royal College of Physicians, this year, on Certain Nervous Affections of the Brain and Spinal Cord, which have been printed in two of the weekly medical papers. The first of these was heard and read with ineffable bewilderment by his grave auditory at the College of Physicians. It was nothing else than a direct manifesto in favor of spiritualism. Mind, he declared, preceded matter, in his belief, and had a separate existence outside it: he inclined to the view that the two were in a mystic relation of cause and effect, mind

being capable both of forming matter and of sphering or encysting itself outside of matter. The whole lecture must be read to be appreciated; but rarely has so much crude hypothesis of undigested metaphysical character been brought before an intelligent professional audience. The lectures were given just before the election of the Royal Society, and, although they have given a great deal of satisfaction to the mass, who regarded them, oddly enough, as having a religious tendency and serving as a protest against "a growing materialism," they have decided unfavorably Dr. Radcliffe's scientific pretensions. Sir Henry Thompson was "up for election;" but this was his "first time for asking," and the Royal Society expects the banns to be put up at least twice, and usually three times.

Apropos of Sir Henry Thompson, it may be mentioned that the current gossip here is that he has been rather "jockeyed" in the matter of the presentation of Napoleon's "sleeve-links in a gold box" to Sir William Gull, which has been solemnly announced in all the papers. Sir Henry had received some very handsome recognitions of the Empress's appreciation of his skill and devotion,—among these, a unique example of ancient Chinese art, a box of great size, in superb "lacquer," part of the spoils of the summer palace of the Emperor of China, removed from Fontainebleau. The Empress had shown it to Sir Henry Thompson during his stay at Chiselhurst, and, as he is an accomplished artist, and lover of art, he expressed his warm admiration of it in terms which showed that his appreciative power was equal to his warmth of admiration. The Empress subsequently requested his acceptance of it, accompanying the box with a graceful autograph letter which conveyed the intimation that the box had been in two palaces,—of China and of France,—the fortune of war had twice uprooted it, and now she hoped he would value it sufficiently to give it a quiet resting-place in the country which was the asylum of kings and the resting-place of the exiled. Sir William Gull gracefully waived, it is stated, all claim to outstanding fees, amounting, however, to a comparatively small amount; and the sleeve-links represent the imperial thanks. Sir Henry refused, it is said, to accept more than one-half of a check for two thousand guineas which was handed to him for his services.

We are now at the Whitsuntide holidays, and thus have notice that the active season is drawing to a close. Already the Pathological Society has ended its sittings, and the other societies are at their last meetings. Parliament has nearly ended its active labors. We are for the most part thankful to it for what it has done in rejecting the proposal to repeal the Contagious Diseases Acts. These Acts, as you are aware, provide that in garrison towns every known prostitute shall be liable to periodical examinations by public surgeons, with a view to prevent and cure venereal affections to which they are liable, and which, through them, cause a large proportion of sickness and inefficiency in the military and naval services. A most fervent and powerfully organized opposition has been carried on now for several years,—so loud, so active, so ubiquitous, and so lavish of expenditure that it reminded one of the political leagues of earlier days; and it was reinforced with great draughts of power by the leading nonconformist clergy, as well as by many dignitaries of the Established Church. Mr. John Stuart Mill and the Rev. F. D. Maurice were the most respectable of the opponents of the Acts; and a great number of ladies, including Miss Nightingale, have waged unceasing war against them. The medical profession were in their favor almost to a man; but a sort of terrorism has been exercised which, it was fully anticipated, must lead to repeal. The women, the laboring-men, and the religious classes having been united in a vigorous crusade against the Acts, it was feared that the members of the House of Commons would succumb in large numbers to the electoral pressure put on them on the eve of the now approaching dissolution of Parliament; but the press has been almost unanimous in supporting the Acts, and the figures which were published prior to the debate were so strongly illustrative of its sanitary benefits that their eloquence reinforced the courage of the supporters of the Acts, and a decisive battle was won in their favor. No doubt, however, the contest will be renewed at the hustings, and some seats will be lost over it.

A bill is before Parliament which will make our vital statistics very complete. They are already highly valuable, and more reliable than those of any other European nation, but they are vitiated by insufficiency of registration of deaths in cases where no medical man has been in attendance. The present bill, which has passed through the House of Lords and is now before the House of Commons, makes the registration of all births and deaths compulsory. It does not, however, provide for the payment of medical men for their certificates, but demands it of them, as a duty to the state; and this view of the case is being energetically contested by the British Medical Association, which possesses great Parliamentary influence. Those of your readers who have a turn for vital-statistical discussions will find, I may mention, a most trustworthy and readable abridgment and analysis of the two heavy folio volumes (pp. 614 and 576) of the last English census in a thin octavo recently published by Messrs. Stanford & Co., from the pen of Mr. James Lewis, of the General Register Office. It is entitled "A Digest of the English Census of 1871." The published official returns of the census of 1871 may be had of the Government printers by those who desire all the details. While mentioning books, I ought to speak to you of one which is not, perhaps, likely to receive the notice which it deserves, owing to its rather abstruse character. It is Haughton's "Principles of Animal Mechanics." The author is the Rev. Professor Haughton, M.D., D.D., F.R.S., Registrar of Trinity College, Dublin. He possesses remarkable qualifications, and has produced a very noteworthy volume. Dr. Haughton is equally accomplished as a divine, a naturalist, a physician, a mathe-

matician, a politician, and a wit. He is, you perceive, a sort of Admirable Crichton,—not by affectation or pretension, but by natural ability and extraordinary quickness of intellect, combined with great industry and general sympathy with all classes of minds. He is perhaps especially eminent as a geometrician and a naturalist. In this book he has worked out by geometrical methods of great beauty and originality the solution of some very difficult problems, and has aimed at completing the work begun by Borelli in 1680, in reducing to mathematical form the laws of muscular and osteological construction in the animal kingdom. Among the more interesting chapters of the book are those in which the author discusses the hip-joint, showing that the centre of the acetabulum is so placed as to allow each muscle to do the maximum of work; that on the arrangement of the fibres of the heart, in which he arrives at a similar conclusion; and the mechanical investigation of the muscles employed in parturition. Dr. Haughton puts forward a great number of proofs of a teleological postulate that "The Framer of the Universe has constructed all muscles on the principle that each shall perform the maximum of work possible for it under the given external conditions." He finds nothing tentative, nothing useless, nothing imperfectly adapted to its obvious end. Contrasted with this it is curious to read another book by a great physicist, which has recently appeared from the English press,—a translation of Helmholtz's popular essay on "Subjects of Physical Science," edited by Professor Tyndall. In the lectures on the eye—which are admirably translated by Dr. Pye Smith—Helmholtz points out so many imperfections in the construction of the human eye as an optical instrument that he concludes that from it the strongest arguments may be derived for the Darwinian theory, since it is only by such a theory that they can be explained. Finally, I think I should mention to you the "Handbook for the Physiological Laboratory," by Sanderson, Foster, Klein, and Brunton, as one of the chief scientific events of the season. It is full of great faults, which have been severely exposed in a long review which has caused a great deal of discussion here; but its merits overpower its faults, and it is admitted on all hands to be the most original and trustworthy book which has yet appeared on the subject in any language, and one which will be invaluable to medical students. It is, however, destined to no very long popularity; for a similar handbook by Professor Rutherford is about to be published, which will probably be much more homogeneous and compact, and will be not less trustworthy, while it will be less bulky and diffuse. Altogether, there is great animation in medical publishing here.

OUR PODUNK LETTER.

Podunk, June.

DEAR TIM,—You will be glad to hear that I am now Health Officer and President of the Board of Health of this metropolis; and I find that your advice to go in for hygiene as a promising lead was sound, as it generally is. I made my first move in the department of ventilation,—got up a new system by putting the openings at the middle, instead of top or bottom; and my new American Universal Ventilator is a success,—can be applied to anything, from a hat to a hospital, and is now being introduced by order of the Board of Health into every chimney and hack in this town. I get three dollars royalty on each one: how high is that? I am now getting up a hygienic cooking-stove with disinfecting attachment, and I don't think there is less than five thousand dollars in it. But to come to the point: I am going to start a daily hygienic journal, *The Podunk Sanitorial Cosmopolitonian*, to be printed on medicated paper and of suitable size. I want you to write some articles for it, urging, from the legal point of view, the necessity for legislation on the subject, and for a Central Bureau of Hygiene; and I want you to write, or get some one to write, an article on the climate of this part of the country as good for cancer and baldness.

The climate changes pretty often and pretty fast,—is hot, and foggy, and damp, and raw, and couldn't be recommended for consumption no way. But there are no cases of cancer here, for the last one died about two weeks ago; and the druggist told me he had three pounds of cundurango left, and no customers; and did I think it might be good for anything else,—such as granular lids, or biles, for instance?

Well—don't you see?—the climate here must be good for cancers, and you can say as much as you like as to its effect on the baldness. What I propose to do for the science of Hygiene is to make it practical, you know,—bring it before the public in such a way that none will know it but to love it, so to speak. The demand of the age is for statistics, and I am going to have some. Take corns, for instance. The average is 1.3007 to each individual. But what a corn-doctor wants to know, and what the spirit of the age demands, is precise data as to the influence of locality, climate, diet, and ventilation upon their growth and development. And the *Cosmopolitonian* will have those data, for I am going to make them.

I shall advocate congressional legislation, of course; and that's where I want your assistance. What I favor is a corps of United States Sanitary Inspectors,—say one for each State and Territory, and a dozen for Europe and Asia. Have a handsome series of blanks prepared, including all possible questions, and let the inspectors report once a month. I suppose there would have to be some sort of a head-centre for them to report to; though there are some objections to it. Depend upon it, that is the system that is going to be established, and you can't do better than put yourself in training for one of the inspectorships by writing some sanitary articles for me. Of course, we must organize and keep out the quacks, who are intruding everywhere: there's one on the Board of Health here, who got the place on the strength of a sanitary tooth-brush with a hollow handle to be filled with hygienic powder, which passes out be-

tween the bristles, on the principle of Mason's potato-drill. I'd like to put one of my ventilators into the side of his head.

By the way, I could get the office of chemist to the board created, and hold it myself, if you can find me a good, competent man for assistant who will run the department and not blow about it.

To return to the organizing. The National Health Association have got the start of us, but they have taken in a number of people who don't care about office, —in fact, who have got good places now,—and, therefore, will criticise and object to all moves which will be of any "practical use" to the organizers.

If I hadn't thrown away time and opportunities I might now, perhaps, be in Washington in a comfortable office as Chief of the National American Republican Sanitary and Hygienic Enforcement and Vitally Statistical Bureau, and, if I was, I can tell you that the N. A. R. S. H. E. V. S. Bureau would be an institution worth caring for. But the bloom has been brushed from that idea, and we will go in on a bigger platform.

Yours, as usual,
D. D. Douceit.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Thursday Evening, May 22, 1873.

The President, Dr. J. H. Hutchinson, in the chair.

Dr. GEORGE C. HARLAN exhibited a specimen of *caries of the tympanum*, and said the case of the patient from whom this specimen was taken was reported in the *Medical Times* in November last (No. 55). She was a delicate girl, 22 years of age, whose mother had died of phthisis. She had been subject to an occasional discharge from the left ear since early childhood, and death resulted from an abscess of the brain following upon a violent attack of otitis, which involved the tympanum, mastoid cells, and external meatus. The abscess was as large as a hen's egg, and rested on the upper surface of the petrous bone, from which it was separated by the membranes and a thick layer of lymph. There was a small opening through the membranes.

Nearly half of the roof of the tympanum from the entrance of the Eustachian tube backwards is destroyed, and the upper part of the posterior wall is gone, the tympanum and mastoid antrum forming one continuous cavity. Nothing remains of the roof of the mastoid antrum but a thin bony scale with large perforations. The outer part of the posterior wall of the external meatus and the bone around it are honeycombed, and contain sinuses leading to the mastoid cell. Notwithstanding the extensive destruction of the walls of the tympanum, the portio dura escaped; there was no facial paralysis, though the nerve was exposed at several points by openings in the aqueduct of Fallopius. The membrane was destroyed, and there was a large polypus just within the tympanum.

The development of the temporal bone is very deficient for an adult. The mastoid process is little more than rudimentary, and the vertical cells are not formed.

The anterior and inferior wall of the meatus is deficient, I believe principally from defective development, as the disease does not seem to have followed that direction to any great extent.

Dr. William Thomson had examined both eyes of Dr. Harlan's patient and found in each "choked disk." In making post-mortem examination they were unable to get the posterior portion of either eye. But he had removed the optic commissure, with a view to determining whether any change was present posterior to the retina in the optic nerve. In comparing sections of this optic commissure with sections of a healthy one, he had found the nuclei of connective tissue much more numerous on the commissure from the affected eye than on that of the healthy one.

Dr. R. M. Bertolet said the diagnosis of brain-disease in connection with purulent disease of the middle ear is very obscure. The symptom of choked disk in this connection was a new one to him; and he thought that even this could not be relied upon, since it is possible to have meningitis without it. The diagnosis of thrombus of the sinus transversus can only be made with certainty when pyæmic symptoms are present,—irregularly recurring chills, evidences of metastatic foci in the lungs, liver, etc. When these manifestations are absent, and we have only symptoms of brain-irritation, which may be dependent upon a concomitant meningitis or encephalitis, then the diagnosis must at best be doubtful. Gerhardt mentions as a pathognomonic symptom that the jugular vein on the same side with the occluded sinus is scantily filled. Nor is this to be relied upon; since post-mortem examinations have revealed thrombus of the transverse and inferior petrosal sinuses existing on the side on which the jugular vein was still well filled. Nor is the symptom of painful œdema of the mastoid process to be relied upon; since we often have thrombus of the sinuses without this, and we frequently have marked swelling over the mastoid process without inflammation of the brain. It is also sometimes difficult to establish the connection between the middle-ear trouble and the inflammatory condition of thrombosis or of cerebral abscess. Some time ago, however, he met a case with caries of the middle ear involving the auricles principally, and on the same side thrombosis. In this case he thought that inflammation and phlebitis of the lateral sinus must have been established by means of the very small veins which run through corresponding openings in the petrous portion of the temporal bone, since the tegmen tympani remained intact.

Dr. James Tyson asked of those interested in this subject whether central nervous disease producing deafness, as a tumor pressing upon the origin of the auditory nerve, was ever found to have been attended by changes in the normal structure of the organ of hearing.

Dr. C. H. Burnett said that he knew of no observations bearing upon this subject except those recently published by Levi, in Paris, who furnishes illustrations of the membrane of the tympanum in certain cases of cerebro-spinal meningitis, in which the membrane had undergone symmetrical changes in color to about one-quarter their extent, assuming in this area (antero-superior quadrant) a chocolate hue. He had himself examined the membrane of the tympanum in several cases of cerebro-spinal meningitis, but discovered no change.

Dr. James Tyson exhibited *a tumor of the cerebral meninges* removed from William K., colored, age 45, native of North Carolina, admitted to the Philadelphia Hospital May 15, 1873, with syphilitic history. When admitted, he complained of muscular pain, more particularly in the flexor muscles of the left arm, which he attributed to rheumatism. There was impaired motion of the left fore-arm, and he said he had been paralyzed; but he could give no account of himself. When first seen by Dr. T., May 16, 1873, he could not or would not

talk, but, muttering, placed his hand to his head when urged to answer. That morning, however, he walked without assistance to the water-closet and into the yard. He could also move all his limbs, though that of the left fore-arm and hand was deficient in power. He continued thus walking about the ward until the afternoon of the 17th, when, having eaten his dinner, he said he felt badly, and went to bed. The captain of the ward, passing the bed a little later, noticed a twitching in the muscles of his face. Half an hour later he became comatose. In this condition his right pupil was largely dilated, the left decidedly contracted, to a pin's point, and there was apparently no motion or sensation. His breathing was stertorous, his pulse 75, and full, and his temperature 98°. He continued thus until the evening of the 18th, when his pulse ran up to 140 and became exceedingly weak, and he died on the morning of the 19th.

Post-mortem examination revealed three adjacent tumors on the under surface of the dura mater, over the right middle lobe, 1½ inches to the right of the median line. The largest of these was as large as an English walnut; the second, of irregular shape, was composed of two portions—a smaller, three lines in diameter, a larger, six lines. The third was a flattened oval mass, eight lines long and four wide.

The specimen was referred to the Committee on Morbid Growths, who reported as follows:

"Your committee, having examined the tumor presented by Dr. Tyson, find it to be a rare specimen of *primary sarcoma* of the cerebral meninges. The origin of the two growths has evidently been from the arachnoid, although the basal portions are pretty firmly adherent to the dura mater.

"The size of each of the tumors is nearly that of a walnut; the consistence soft.

"The cells are principally of the spindle-shaped variety, with here and there giant cells (myloplaques). The intercellular substance is scantily developed. Numerous blood-vessels exist in all parts of the growth; while there is a remarkable absence of any pigmentary cells."

Dr. TYSON also exhibited a specimen of *gastric ulcer perforating a blood-vessel, from which hemorrhage and death ensued*, removed from J. D., age 31, born in Germany. His father and mother were living five years ago; he has not been a drunkard; he contracted syphilis in 1865, and secondary symptoms appeared later.

In July, 1872, he first noticed a "fulness" in the stomach, with pain in the left side. This continued until a week before Christmas, when he vomited about a pint of dark, black blood, which came up in "lumps." The hemorrhage was preceded by vertigo.

About a week after Christmas he had a similar attack of vomiting. He has been feeling badly ever since he had this first vomiting of blood, but was able to be about until last Thursday (May 8, 1873), when he had another attack of vertigo of about five minutes' duration. After the vertigo passed off he vomited a large quantity of dark, black blood, which amounted, according to his own statement, to nearly a gallon. He was admitted to the hospital May 12, 1873, when he was exceedingly weak and anæmic.

His bowels were always constipated, and he complained of a "burning fulness" about fifteen minutes after eating, and especially after taking solid food.

There was no pain on pressure, except at a small spot to the left of the epigastric region.

On May 14, 1873, he vomited thirty-four ounces of dark, clotted blood, and soon afterwards died.

The post-mortem examination revealed the presence of a gastric ulcer in the larger curvature of the stomach, about three inches from the cardia.

The stomach contained ten ounces of coagulated blood. The head of the pancreas was decidedly hard, containing nodular deposits, the exact nature of which was not determined.

The brain, kidneys, and liver were exceedingly anæmic.

Dr. F. H. GETCHELL exhibited a *calculus three inches long, one and a quarter wide, and three-eighths of an inch in thickness, formed about a hair-pin as a nucleus*, which he had that day removed from the vagina of a girl aged nineteen. Towards one end of the calculus was a concavity, into which was adapted the neck of the uterus.

Dr. H. LENOX HODGE said that he had often found pessaries thus incrusted, and in these instances there was reason to believe that the incrustations were due to deposits from urine.

Dr. GETCHELL said this calculus was removed from a woman who was a chamber-maid, whose occupation required her to be more or less constantly on her feet.

Dr. J. EWING MEARS mentioned a case which had come under his observation, in which a surgeon removed from the vagina a pessary which had been in position over nine years, which had a coating of inorganic matter. The coating was much thinner than that of the specimen under discussion. He could not say whether this was due to any difference in the material of the substance upon which the deposit formed. He had himself removed a glass pessary which had remained in the vagina for fourteen years. This had also but a slight coating.

Dr. TYSON said there must be extraordinary differences in the quality of the secretions of different females, since he had recently removed a pessary which had been in the vagina eight years, which on removal was as free from deposit as it must have been at the moment of introduction.

Dr. JOHN ASHHURST, JR., said that in considering the different rates of deposit noted in connection with these vaginal accumulations (which he suspected were really derived from the urine in most instances), it should be borne in mind that the rate of urinary deposit in the formation of vesical calculi was also very different in different cases. It sometimes happened that the deposition from phosphatic urine was so rapid that in attempting to remove a stone by lithotrity it was found that the accumulation in the intervals between the sittings actually exceeded the amount removed at each operation. So also when foreign bodies were introduced into the bladder by accident or otherwise, the rate at which concretions were deposited was by no means constant, the foreign bodies sometimes soon assuming a large size in consequence of such deposition, while in other instances they remain a long time with little or no incrustation.

Dr. HODGE said that in corroboration of these remarks he might say that he once removed from the bladder of a female the end of a female catheter which had been in the organ twelve years, and it was totally without incrustation, being simply blackened.

Dr. GETCHELL had also removed from a female the end of a catheter which had been in the bladder twelve years. It also was without incrustation and simply blackened.

Dr. C. H. BURNETT asked whether a loss of substance did not sometimes occur in pessaries while in the vagina, since a case had recently come under his observation in which this appeared to have taken place.

Dr. HODGE said that before the introduction of the hard-rubber lever pessaries, nothing that could be used in that shape had been found to resist the corrosive action of the fluids of the vagina except gold, and that only for a short time. The corrosive power, however, is very different in different women.

Dr. HODGE also stated that previous to the hard-rubber his father had used silver, plated as thickly as he

could get it with gold, and that it was in compliance with an urgent request of his father to devise something that would not be thus acted upon, that he himself suggested the hard-rubber. The first pessaries used were the hard-rubber rings made for the harness of horses.

The specimen was referred to a special committee, composed of Drs. H. B. HARE and JAMES TYSON, for examination and report.

The committee reported as follows:

"The committee appointed to examine the calculus removed from the vagina by Dr. F. H. Getchell report that the exterior is composed solely of phosphate of lime. The committee regret that they were not permitted to make a section of the stone, as the examination confined to its superficial portion adds nothing to the value of the specimen and makes it a mere curiosity."

Dr. GETCHELL also exhibited a small *breast-pin* which he had removed from the vagina of a young girl.

Dr. GETCHELL also presented a specimen of *albuminous urine* from an adult male, in which no one had heretofore found casts, although the quantity of albumen was considerable.

This specimen was also referred to Drs. HARE and TYSON, who reported as follows:

"The committee to which was referred the specimen of albuminous urine presented by Dr. F. H. Getchell report that it contains a bulk of albumen equal to about $\frac{1}{10}$ of that of the fluid tested, and that in it were found a few granular casts. It believes the case to be one of contracted kidney."

Dr. DE FORREST WILLARD presented, for Professor D. H. AGNEW, a *contracted liver* from A. B., 60 years of age; a frequenter of club-houses during life; constantly drinking to excess, but never to intoxication. His health had been slowly failing for the last five years, but he was not confined to the house until about six months before death. Ascites and œdema of lower limbs became very troublesome during the last four months of life, and strength gradually failed. He was tapped in March, and several gallons of liquid drawn off. The abdominal distention soon returned, however, and he died in the middle of May, from exhaustion and peritonitis.

Autopsy.—Peritoneal cavity filled with several gallons of bloody serum. At brim of pelvis, at various points in the iliac fossæ, and in the lumbar regions were blood-clots, some of them an inch and more in diameter, others smaller. They were mostly within the peritoneal cavity, but a few were found in the subperitoneal connective tissue. Those lying upon the peritoneum were confined and enclosed by a layer of lymph. Throughout the entire surface of the membrane, both parietal and visceral layer, were bands of lymph which bound all the intestines and every abdominal organ firmly into one mass. Careful and accurate search was made to ascertain whether an abnormal blood-vessel could have been situated directly in the median line; but no trace of one could be discovered, and it seemed evident that the hemorrhage had occurred from capillary oozing, possibly due to the removal of pressure from the vessels by the previous tapping, although a bandage had been applied during the operation. The liver was so exceedingly contracted that it had lost all resemblance to such an organ, and was merely a hard, round ball about the size of one's two fists. The left lobe had been so entirely removed that scarcely a trace of it remained. The connective tissue preponderated greatly over the hepatic; in fact, there was but little of the latter substance remaining. A thick layer of lymph covered in the whole organ and its gall-bladder, giving it an appearance which rendered recognition almost impossible. Upon section it was dense, firm, and tough; the spleen was greatly enlarged, being seven or eight inches long, five wide, and two and a half thick. It was also so condensed and firm that upon section it appeared of the density of the liver in health, and presented all the appearances of that organ to the unaided eye. Under the microscope the structure was found to consist almost entirely of connective tissue, but few splenic elements being present.

The kidneys were deeply congested, slightly enlarged, fatty, and in the pelvis of the left was about one-half drachm of pus.

The stomach bore, upon superficial examination, no decided evidences of disease.

The visceral layer of the pleura of the left lung was bound to the parietal layer by strong, firm adhesion.

Right pleural cavity filled with liquid, and both lower lobes of lung collapsed.

The heart was small, but valves healthy. Brain not examined.

Dr. TYSON, in allusion to the hemorrhage spoken of as having occurred at the tapping, referred to a case related to him by Dr. William Pepper, in which abdominal tapping was practised for ascites attending hepatic disease, and, after a considerable quantity of fluid had been drawn off, bloody serum began to flow, followed soon by a flow of pure blood. After a short time the tapping was discontinued, the opening closed, and no bad symptoms followed. This was explained by the removal of previous pressure from the capillaries, in consequence of which the leakage took place.

Dr. JOHN ASHHURST, JR., referred to the fact that similar accidents had occurred in tapping large serous cysts, from which, after the evacuation of the cystic fluid, there was sometimes a flow of bloody serum, and ultimately of pure blood, and added that in such cases, unless care was taken, serious consequences might actually ensue from the hemorrhage. The explanation of the occurrence was, of course, that capillary bleeding followed the sudden diminution of pressure, and a like accident might, Dr. Ashhurst thought, well occur after paracentesis of the abdomen, particularly if the precaution of employing a bandage during the operation had not been observed.

Dr. H. LENOX HODGE exhibited the *head and neck of femur removed by excision in a case of coxalgia.* The operation was performed at the Children's Hospital on Wednesday, May 14, and thus far the patient has done exceedingly well. He is a boy, eleven years of age. His mother died of consumption. His father is alive, and in good health. He was admitted to the hospital about one year ago, and during a portion of the summer was sent to the Hospital for Convalescents, at Atlantic City. A few months ago an abscess formed, which pointed, on the front of the thigh, and still remains open. The head of the femur was out of the acetabulum and drawn backwards on the ilium. Ulceration had nearly destroyed the head of the bone, and the under surface of its neck was bare, the periosteum having been separated. The anterior and inferior portions of the rim of the acetabulum were extensively diseased, having sharp edges and being uncovered by the periosteum.

Dr. WILLIAM DARRACH exhibited the *arteries from the base of the brain, from a case of softening with hemiplegia.* The patient's age was 62; he was temperate, a bachelor, a gentleman of leisure and means. On October 14, 1872, he was taken sick at his hotel about 5 o'clock P.M. He was carried up-stairs to his room unconscious. At 8 P.M. a physician saw him; he was still unconscious; cups were applied, and he was bled. At 8 A.M. he was conscious, and hemiplegic on the right side. The paralysis continued until about the latter part of November; he then walked about, came down-stairs, and even engaged in a game of croquet. In the middle of December he grew worse, and again lost power of limbs; very restless and excited at night; he

imagined himself in the street; his dreams were realities to him; but during the day his mind seemed clear about his affairs; he realized his critical condition, and gave his brother power to act for him; he told his sister what he desired to do with his property, and seemed anxious about his condition: he said he would not get well. *Aphasia* was a prominent symptom; restlessness at night; occasionally great irritability; nausea in the morning. Pulse about 80, sometimes intermittent. At times he seemed to suffer pain in the right shoulder; he never complained of headache, but sometimes of pain in the bowels. There was occasionally spasmodic action of the muscles of the left arm and leg during the last two days of his sickness.

The *breathing* was *peculiar*,—*heaving* like a woman's. The day before his death he seemed very much depressed, and spoke of his disease as real estate, and of himself as a third person; but still, the day before, he told about his own case, and asked the difference between palsy and paralysis.

Post-mortem.—Brain.—Opacity, and deposits in pia mater of both hemispheres. The left lateral ventricle contained a yellowish-white mass in the corpora striata. Considerable effusion, with great softening.

The arteries showed marked abnormal condition along their whole course. The vessels seemed much thinner in some parts than in others.

The *basilar artery* was flattened, and of a yellowish color, the walls very much thickened at some parts and thin at others.

The communicating arteries appeared to be merely fibrous.

The carotids were also thickened, especially the right.

From these appearances the case was looked upon as one of softening from anæmia of the brain, caused by degeneration of the coats of the blood-vessels.

The coats of the vessels were found to contain a great deal of fat.

The softening in the left ventricle was no doubt the cause of the attack in the month of October.

The heart was hypertrophied, but the valves were normal.

The liver was normal.

The kidneys were granular.

Dr. MEARS presented a *multilocular ovarian cyst*, removed by Dr. Washington L. Atlee from a patient æt. 42 years. The tumor involved the right ovary, and consisted of one large cyst, with several small cysts developed in the posterior wall. An interesting feature connected with the specimen was the quantity of fluid contained in the large cyst, measuring sixty-four pints. The fluid was of a deep chocolate color, highly albuminous, very viscid; specific gravity 1030. Under the microscope it showed a large number of blood-corpuscles, granular débris, and compound granule-cells.

Dr. HODGE asked whether anything had occurred in the prior history of the case to give rise to the presence of such bloody fluid, such as a fall or similar cause which could rupture the blood-vessels of a cyst.

Dr. MEARS replied that nothing of this kind had occurred, so far as he could ascertain.

REVIEWS AND BOOK NOTICES.

OPHTHALMIC CONTRIBUTIONS.—I. DERMOID TUMOR OF THE CORNEA. II. AN ADDITIONAL METHOD FOR THE DETERMINATION OF ASTIGMATISM. III. CYST OF THE IRIS, REMOVED BY OPERATION. By GEORGE STRAWBRIDGE, M.D., Lecturer on Diseases of the Eyes at the University of Pennsylvania, etc., etc.

The first paper gives an account of a dermoid cyst removed from the cornea by an operation, with a good result, and adds one more to the cases already on record. The second describes a clinical method of examination of astigmatism which combines those advised by Donders, Snellen, and Dr. Green, in a simple and useful form. The third recites the clinical results of a successful operation for the removal of a cyst of the iris, and gives a short résumé of the literature of the subject. These papers are tersely written, and form a valuable contribution to ophthalmic surgery.

SELECTIONS.

SIR JAMES PAGET ON THE TREATMENT OF BED-SORES.

FIRST of all, look to the bed. Good bed-making is an indispensable thing in the prevention of bed-sores. Several beds have been made especially for this purpose, of which the best is Dr. Arnott's. It consists of a chest full of water; on the top of this is a water-proof sheet, and over this an ordinary sheet on which the patient is laid. Here the patient is absolutely floating on water. The waterproof sheet is not drawn tight, but adapts itself to every part of the patient. A patient might lie on this for years and never have a bed-sore. Inferior to this, but very good, is Hooper's bed. Here the waterproof on the bed is tight. They will avert bed-sores for a long time, but I should not like to say that a patient would never get a bed-sore on them. But you cannot have these everywhere; you can't take them about to every one who may need them, and there are many cases in which they cannot be used at all, as in cases of fractured neck of femur, acute inflammation of knee-joint, and many others.

In ordinary beds the best thing is an ordinary firm mattress of horse-hair; and it must rest on boards. Cords are the worst possible things; as after twenty-four hours or so they give under the weight of the patient, and the most prominent parts are pressed upon. Iron gives after two or three weeks. Not so boards. It must be quite level. Under the horse-hair it is better if possible to have a spring or straw mattress. Feather-beds and the like are, of course, to be utterly condemned. If possible, have two beds, so that you may lift the patient into the other when it wants making. You thus avoid making beds under him.

The next thing is to harden the skin. The best application for this is a solution of one part of nitrous ether in three of water. If the back is frequently washed with this, bed-sores may be completely averted. There is in the hospital a man paralyzed in his lower limbs; he has been in this state for ten months. By the good nursing of the sister of his ward, bed-sores have been kept away. This application of nitrous ether has been used. Solution of one grain of perchloride of mercury, with two drachms of nitrous ether, and six ounces of water, is another good thing. Whisky is used in Scotland, as is brandy sometimes in England; but these are not so good. In Germany they use a solution of tannic acid. When the parts look as if they were going to slough, these spirit applications may be too strong, and then a solution of gutta percha in chloroform is very useful. Next we have to prevent pressure on those parts where bed-sores are likely to occur. These are the middle line of the sacrum, after that, in thin persons, the posterior-superior spines of the ilium, and the sacro-iliac articulations, then the trochanters of the femur. The chief thing is a frequent change of posture. If a patient can lie in four different positions during the day, bed-sores may be prevented. He may lie on his back, each side, and on his face. Of course, you couldn't make a stout person lie on his face: he

would simply suffocate. This change prevents the gravitation of the blood. This may easily be seen by looking at the back of a subject in the post-mortem room. The back is quite red from this cause.

When patients lie on their backs, they may be saved for a time by dividing a mattress and leaving a space of six inches between the halves. You may thus save the sacrum, which will have no pressure on it. The case before referred to was treated so, but sores came on the ilium and trochanters.

Large cushions made of amadou in the shape of a horse-shoe are very good. Pads of cotton wool may also be used with advantage. In speaking of the mode of curing bed-sores already formed, let me remind you to continue your preventive treatment just as if there were none, lest they come in other parts.

During the sloughing there is nothing better than a poultice of equal parts of linseed and bread and enough charcoal to have a deodorizing effect. Carrot and turnip poultices are also deodorizing, but they are not so good as the first. The poultice is best spread on ordinary tow. When spread on linen, etc., folds are liable to form, and if the patient is on these they promote the bed-sore. When slough begins to separate, the resin or other stimulating ointment should be spread on the surface of the poultice.

When the slough has separated, the sore should be dressed with resin ointment or Peruvian balsam, or equal parts of these, in the following manner: little bits of cotton wool should be slightly spread with the ointment, and put into the sore until it is quite full. They thus make an equable soft surface for the sore. These are the chief local means for curing bed-sores. As regards internal treatment, don't stimulate. Let the diet be gentle but good; plenty of milk and bread, little or no meat, and a small quantity of wine. — *The Student's Journal.*

GLEANINGS FROM OUR EXCHANGES.

On the Relations of Faradaic Electricity to Pain.—Among the varied and important therapeutical uses of electricity certainly one of the most prominent is the relief of pain; and, as pain is so common and often so troublesome a thing to deal with, it is natural that practitioners should eagerly seize hold of what promises to be a new mode of relieving it, without inquiring very minutely as to the precise conditions upon which success depends. One of the most fruitful causes of failure and disappointment in this connection is the neglect to discriminate between cases requiring the use of the continuous current and those in which faradization is the suitable remedy. An excellent article in *The Practitioner* for June defines as follows the boundaries of usefulness of the latter therapeutic agent:

1. Faradization is useful as a *mental counter-irritant* in "hysterical" conditions when the mere concentration of attention on a particular part of the body will convert some slightly unusual sensations into the mental perception of actual pain.

2. Where the so-called "hysteric hyperæsthesia" exists, large mucous or cutaneous areas being unnaturally sensitive to superficial pressure.

In both these cases the skin should be dried, and the current applied unsparingly with dry conductors, one pole being placed over an indifferent spot, the other moved slowly about over the area to be operated upon.

3. Where the pains are situated in the muscular or tendinous structures and are closely connected with the degree in which the muscle has been over-exerted in proportion to its nutrition, faradization will usually remove them. Its action here must be strictly limited to the skin, by having the latter very dry, and using only dry conductors, as, if the current penetrate to the muscle and set up contractions, we shall only add to the agony.

4. In chronic fibrous rheumatism seated in the ligaments of joints, in fasciæ, and in periosteum, faradization may do good; but no positive results have yet been obtained.

5. In true neuralgia obviously following the track of a recognizable nerve, faradization is either useless when it does not penetrate beneath the skin, or hurtful when it brings on muscular contractions, as there are no such terrible exciters and aggravators of neuralgic pains as repeated intermittent impulses.

In regard to the regularity of the interruptions in the current, it may be said that in proportion as the malady is beyond the patient's own control it is desirable to employ a regular series of intermissions, and *vice versa*. That is, with a patient having none of the common convulsive phenomena of hysteria, but with some definite paralysis or anæsthesia, and whose skin presents a patch of acute tenderness, use a tolerably intense current with rapid and even intermissions. The patient should be placed under chloroform, and the dried skin should be well fustigated with the wire-brush of a Stöhrer's or Weiss's faradizer, the secondary current being employed of high strength. If the affection be one in which the morbidness of the will has much to do with the painful sensations themselves, no chloroform should be allowed. The electrodes should be brass disks, and a common magneto-electric apparatus may be employed, the current being arranged at a high degree of intensity, and the driving-wheel urged at a varying and irregular pace.

What are the Signs of Congenital Syphilis?—In a paper read before the Harveian Society of London (*Lancet*, May 24), Dr. Thomas Ballard discussed the subject of congenital syphilis, and endeavored to show that those conditions before birth, at birth, or some time after birth, which have been supposed to depend upon a syphilitic taint, can be explained by simpler and more obvious means. Acknowledging that a woman infected with syphilis is apt to abort and bring forth dead children, he denies that this is from the direct effect of the virus upon the fœtal organism, and asserts that "the death of the fœtus in utero is the consequence of some defect in the maternal system, resulting from its contamination by the syphilitic virus, and that it is not necessary to infer, neither is there evidence to prove, that the organism of the child is intrinsically affected by it." He believes pemphigus and other forms of erysipelatous disease occurring within a fortnight after birth to be pyæmic affections resulting from unhealthy suppuration of the umbilicus; and the coryza, thrush, and ophthalmia of new-born children to be due to external irritants, as cold air, sore nipples, and exposure to light. He thinks the cutaneous inflammations about the buttocks and thighs are usually caused by the contact of moist and frequently unclean flannel, and relates cases where such troubles disappeared in a few weeks after the mere removal of the napkins, though they had resisted anti-syphilitic treatment for many months. He concludes that "the records of cases of living children having been born with manifestations of syphilitic disease are so few as to allow of the supposition that they are not trustworthy," and that "the symptoms which are developed some weeks after birth, and are relied upon as pathognomonic of syphilitic contamination of the system of the child, are mere accidents arising from certain unfavorable conditions to which the child is exposed, and that they are all preventable or easily cured when the cause producing them is recognized."

Snake-Poisoning in India.—The intravenous injection of ammonia in sufferers from snake-bite having unfortunately failed in India (whatever may have been its success in the hands of its originator, Dr. Halford, in Australia), renewed attempts have been made to counteract the poison by Prof. Fayrer, of Calcutta, than whom there is no higher authority on the subject. By a long series of experiments he has ascertained that while none of the so-called "antidotes" are of any avail, life may be prolonged and ultimately saved by artificial respiration. Dr. Fayrer found a strong analogy between the action of cobra poison and that of curara, the cure for the latter being the application of warmth to the body and artificial respiration. In this way, after apparent death for many hours, the poison is eliminated by the excreting organs, and the victim recovers. Curara paralyzes the peripheral expansion of the motor nerves, inducing asphyxia in the muscles of respiration. Cobra poison acts similarly, though Dr. Fayrer fears it may also do irreparable injury to the nerve-centres. Dr. Fayrer believes that, whatever the result when an overwhelming quantity of poison has been received, those cases in which a smaller quantity has been injected, and which, if left to themselves, would die, may by artificial respiration be saved. Acting on his suggestion, Mr. Richards, civil medical officer of Balasore, in the case of a dog, sustained the heart's action for ten hours, though convulsions had set in when he commenced artificial respiration. In another case he kept up the heart's action for twenty-four hours and thirty-five minutes. "The eyes had lost the glazed appearance, lachrymation was restored, and there was a winking of the lids on dropping water into the eye, attempts at deglutition when water was put into the mouth, and the heart beating vigorously."—*London Lancet.*

Case of Complete Aphasia followed by Cure.—This interesting case is recorded by Dr. Grasset in the February number of the *Montpellier Médical.* The author has thus briefly summed it up: "A man with inveterate alcoholic habits, and presenting unmistakable signs of alcoholism, was suddenly affected, in the midst of perfect health, with vague malaise and gastric troubles, which he ascribed to indigestion; then suddenly, during a quarrel, he lost the power of speaking, was admitted the following day into the hospital, and then showed utter inability to express his thoughts in words or writing or by gestures. The intellectual faculties seemed entirely preserved, and all the movements were free, though there was slight hemiplegia of the left side. The phenomena gradually abated under the influence of revulsant treatment, and remarkable progress towards cure manifested itself one night after three attacks of epistaxis. From that moment recovery took place rapidly. Only, during convalescence, a sort of hemiplegia of the various senses was observed; but these phenomena gave way in turn, and the patient was dismissed, entirely cured, on the twenty-seventh day after the onset of the disease."—*London Lancet.*

Rheumatism of the Gravid Uterus.—Dr. E. H. Trenholme reports a case (*Canada Medical Record*, June) of rheumatism of the uterus occurring in a multipara during the sixth month of gestation. A sudden and severe attack of sub-acute rheumatism of the right shoulder was followed by agonizing epigastric and diaphragmatic pains, which were succeeded by tenderness and swelling of both knees. At this stage the uterus became the seat of the most intense agony, the other symptoms abating. The uterine pains continued for five days, resisting treatment by morphia, aconite, and powerful counter-irritation, but yielding finally to a mixture of iodide of potassium, bicarbonate of potassium, and wine of colchicum.

MISCELLANY.

Medical Prizes—Boylston Prize.—At the annual meeting of the Committee, held June 2, 1873, it was voted that prizes of one hundred and fifty dollars each be awarded to David F. Lincoln, M.D., of Boston, for a dissertation on "Electro-Therapeutics," and to William C. Dabney, M.D., of Charlottesville, Va., for a dissertation on "The Value of Chemistry to the Medical Practitioner."

The following are the questions proposed for 1874:

1. The Best Methods of Preventing the Development and Spread of Smallpox.

The author of a dissertation on this subject, considered worthy of a prize, will be entitled to a premium of two hundred dollars.

2. The Development and Extension of Malignant Disease.

The author of a dissertation on this subject, considered worthy of a prize, will be entitled to a premium of one hundred and fifty dollars.

The following are the subjects proposed for 1875:

1. Original Researches in Medical Science.
2. So-called "Concussion of the Spine."

The author of a dissertation considered worthy of a prize, on either of the subjects proposed for 1875, will be entitled to a premium of one hundred and fifty dollars.

Dissertations on these subjects must be transmitted, as above, on or before the first Wednesday in April 1874 and 1875 respectively.

Sneezing.—The custom of invoking a blessing upon persons who sneeze is, says Dr. Seguin, in a recent article on sneezing (*Archives of Scientific and Practical Medicine*), a most interesting one. Several old medical authors state that the custom dates back from the time of a severe epidemic (in which sneezing was a bad sign) during the pontificate of Gregory the Great. Brand, however, and the author of an article in "Rees's Cyclopædia," state that the phrase "God bless you," as addressed to persons having sneezed, is much more ancient, being old in the days of Aristotle. The Greeks appear to have traced it back to the mythical days of Prometheus, who is reported to have blessed his man of clay when he sneezed. In Brand the rabbinical account is given, that the phrase originated in the alleged fact that it was only through Jacob's struggle with the angel that sneezing ceased to be an act fatal to man. In many countries, sneezing has been the subject of congratulations and of hopeful augury. In Mesopotamia and some African towns, the populace are reported to have shouted when their monarchs sneezed. Sometimes, moreover, it is very important not to sneeze; and Dr. Seguin has discovered, what has been discovered before but is insufficiently known, that sneezing may be prevented by forcibly rubbing the skin below and on either side of the nose. And on this observation of himself, and of Marshall Hall, Diday, and the world generally before them, he bases an ex-

ceedingly interesting study of the physiology of sneezing in health and disease.—*London Medical Record.*

To Extract Grease-Spots from Books or Paper.—Gently warm the greased or spotted part of the book or paper, and then press upon it pieces of blotting-paper, one after another, so as to absorb as much of the grease as possible. Have ready some fine, clear essential oil of turpentine, heated almost to a boiling state; warm the greased leaf a little, and then with a soft, clean brush wet with the heated turpentine both sides of the spotted part. By repeating this application the grease will be extracted. Lastly, with another brush dipped in rectified spirits of wine, go over the place, and the grease will no longer appear, neither will the paper be discolored.—*The American Chemist.*

The Disorders of Diplomatists.—Talleyrand, it is said, spent a sleepless night in trying to discover what another diplomatist meant by having the scarlet fever. Pope Innocent XI. was always seized with a violent fit of coughing whenever Castlemaine, the English ambassador, pressed him for a cardinal's hat for Father Petre, the confessor of James II. Just before the Crimean war, the French ambassador at St. Petersburg, while awaiting important dispatches, very conveniently caught a rheum and housed himself. For two weeks, said a witty Frenchman, a pocket-handkerchief was the *drapeau de la France.*

Fecundity of the Mule.—A case of exceptional fertility in this hybrid is mentioned in the *Gazette Hebdomadaire de Médecine* for March, as having occurred recently at Orleansville, in the department of Algiers. A mule has given birth to a young mule perfectly formed. The medical men of the place have ascertained the fact, of which, indeed, many other examples have been recorded. What would be especially interesting would be to know whether this young mule will be fertile.

Medical Department, University of New York.—Professor Charles L. Ives, of Yale College, has been elected to fill the chair of Diseases of the Mind and Nervous System, in the Medical Department of the University of the City of New York.

To Remove Nitric Acid Stains from the Hands.—Wet the skin with sulphate of ammonia to which has been added some potash lye. This changes the dead skin into a soapy mass, which can easily be removed with sand or fine pumice-stone.—*Druggists' Circular.*

A Doctor recently went out for a day's shooting, and, on coming home, complained that he hadn't killed anything. "That's because you have not been at home attending to your legitimate business," replied his wife.

Puerperal Fever has been so prevalent in New York of late as to compel certain practitioners to send their patients out of town to be confined.

Weekly Return of Deaths and Interments in Philadelphia for the Week ending Saturday, June 28, 1873.

The surface of the cistern of Barometer is located 71.92 feet above the mean level of the sea.

Barometer corrected for temperature, elevation above sea, and instrumental error.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 24, 1873, TO JUNE 30, 1873, INCLUSIVE.

Hartsuff, Albert, Assistant-Surgeon.—Assigned to duty at Sidney Barracks, Nebraska. S. O. 107, Department of the Platte, June 21, 1873.

Miller, George McC., Assistant-Surgeon.—When relieved by Assistant-Surgeon Delany, to comply with S. O. 113, c. s., A. G. O. S. O. 117, Department of the South, June 25, 1873.

Azpell, Thomas F., Assistant-Surgeon.—Granted leave of absence for six months on Surgeon's certificate of disability, with permission to go beyond sea. S. O. 124, A. G. O., June 20, 1873.

Delany, Alfred, Assistant-Surgeon.—Assigned to duty at St. Augustine, Florida. S. O. 117, c. s., Department of the South.

SATURDAY, JULY 12, 1873.

ORIGINAL LECTURES.

A LECTURE

ON EPIDEMIC OR MALIGNANT CHOLERA.

BY ALFRED STILLÉ, M.D.,

Professor of the Theory and Practice of Medicine in the University of Pennsylvania.

UNTIL 1830, the inhabitants of Europe and of America were in the habit of regarding the stories of terrible epidemics which devastated Europe in the Middle Ages as belonging to the history of a time which had only a remote, and merely intellectual, interest for the present generation. But a pestilence as terrible as any which the annals of our race record was soon to sweep like a deluge of desolation across the world. On the 9th of August, 1817, it began its death-march at Jessora, a city of Hindostan, whence it advanced to Calcutta, Madras, and Bombay. In the following year it reached the Eastern Archipelago, and in the island of Java, alone, decimated the entire population. Thence it spread into China, and in the course of 1820 entered the northern capital, Pekin. About the same time it began its western progress, ravaged Persia and Arabia, and in 1822 extended as far west as Tripoli, on the shores of the Mediterranean Sea. In the following year the disease showed itself on the northern shore of the Caspian Sea, where it subsided, and appeared for a time to have suspended its progress, for until 1829 we hear no further of its ravages. The pestilence seemed rather to have retired to its original lair upon the banks of the Ganges. But in 1829 it again broke forth upon its old track, eastward and westward, and in the following year we find it raging again around the shores of the Caspian. But this time it did not pause there. It invaded Russia, destroyed more than four thousand persons in Moscow in the space of two months, advanced to St. Petersburg, Warsaw, and the Baltic ports, and appeared in Berlin, Vienna, and Hamburg at the close of 1831. Early in the following year it invaded Great Britain at its northern part, and, while spreading through this and the neighboring island, broke out in Paris on the 26th of March, and spreading throughout France destroyed 120,000 persons in the course of the year. The steady progress of the pestilence westward rendered it probable that it would soon pass the ocean and visit our own shores. Anxiety and dread filled the hearts of the population, and in all directions the municipal authorities prepared to remove the causes which were supposed to favor the development of the disease. It soon became evident that these apprehensions were far from premature. The first case of cholera on the American continent occurred at Quebec, on the 8th of June, 1832, and the disease had reached New York by the 24th of the same month. In the course of a year it destroyed 3500 inhabitants of that city. It was introduced into Quebec by five vessels from Europe, which had together lost 179 passengers by cholera during the voyage.

"All these ships and their passengers were quarantined at Grosse Isle, a few miles below Quebec. On June 7 the St. Lawrence steamer Voyageur conveyed a load of these emigrants and their baggage, some to Quebec, and the majority to Montreal on the 10th.

"The first cases of cholera in America occurred in emigrant boarding-houses in Quebec on the 8th, and the same pest steamboat, the Voyageur, landed persons dead and dying of cholera at Montreal, a distance of two hundred miles, in less than thirty hours; and over this long distance, thickly inhabited on both shores of the St. Lawrence, cholera made a single leap, without infecting a single village or a single house between the two cities, with the following exceptions: A man picked up a mattress thrown from the Voyageur, and he and his wife died of cholera; another man fishing on the St. Lawrence was requested to bury a dead man from the Voyageur, and he, his wife and nephew died. The captain of a passing boat requested an Indian to bury a man from on board; this and five other Indians were attacked and died.

"The town of Three Rivers, half-way between Quebec and Montreal, forbid steamers to land, and escaped for a long time.

"From Montreal the great influx of emigrants was forwarded away, by the Emigrant Society, as fast as they arrived, and by them the pestilence was sown at each stopping-place. Kingston, Toronto, and Niagara soon became affected. In the end over 4000 persons died of cholera in Montreal, and more than an equal number in Quebec."

From the points mentioned the epidemic extended first to Philadelphia, Baltimore, Washington, and the Southern cities generally. In 1833 it broke out in the West Indies, and thence invaded the towns upon the borders of the Gulf of Mexico. In the following year it prevailed in the provinces on our northern borders and in the State of New York, and spread over the whole country during 1835 and 1836. From this period it rapidly subsided, and, although for a year or two cases occurred here and there, the disease had no longer an epidemic character, nor was it of a malignant type. Gradually it disappeared, and the impression became general that we had done with the formidable invader. For nearly ten years this consolatory reflection was entertained; but towards the close of that period the certain though distant signs were visible of its return to our shores.

In 1845 it was known to be advancing on its former path, which it steadily pursued, and entered England in October, 1848, at Sunderland, the very town at which it first appeared in 1831.

"During the second epidemic in Europe, in 1848, two vessels sailed from Havre, where cholera prevailed; one the New York, for New York, and the other the Swanton, for New Orleans. Both contained large numbers of German emigrants. On one the cholera appeared when sixteen days out, with

fourteen deaths; on the other in twenty-six days, with thirteen deaths. The New York arrived at Staten Island, December 2, 1848, and a severe epidemic broke out, but was confined to the Quarantine grounds. The Swanton arrived at New Orleans, December 11; no quarantine was instituted, and in two days patients were taken into the Charity Hospital. This was the beginning of a severe epidemic, which increased in power all winter, till in June, 1849, 2500 died of it in New Orleans. December 20, 1848, it reached Memphis, by steamboat from New Orleans, where for twenty-five days it was confined to the landing-place, but then spread. In the spring it was carried to St. Louis and Cincinnati and the whole Mississippi Valley. In October it reached Sacramento, by means of overland emigrants, and almost at the same time by the United States steamer Northerner, from Panama. The Chinese of California suffered most severely."

In the following April (1849) it reappeared in the public stores at the Quarantine station, Staten Island, and in the succeeding month in the city of New York. From New Orleans in the South, and New York in the North, the cholera spread over the continent, and was even more destructive than during its first invasion. In New York City alone the deaths exceeded 5000. Another pause ensued, which was not broken until the spring of 1854. As before, the starting-point of the epidemic was in Asia. In Teheran, a city of Persia, 11,000 persons perished. It ravaged the South of Europe, destroying an incredible number of victims. At Messina alone upwards of 12,000 are said to have fallen. In France nearly 114,000 were cut off during the year, and in England about 16,000.

Cholera patients arrived at New York in the month of May, 1854, from Europe, and the epidemic straightway commenced. It prevailed during about three months, and destroyed nearly 2000 persons. In Philadelphia during the same period the mortality exceeded 500. I need not trace the further progress of the epidemic, which in this country was less fatal than that of 1849: suffice it to say that it extended to many towns in New England and westward, along the great channels of immigration, through the United States and Canada. Thirteen hundred persons perished at Montreal, and in the small town of Detroit the deaths amounted to 1000.

Once more (December, 1864) the pestilence went abroad. The immediate occasion of its dissemination appears to have been a great Mohammedan festival which was held at Mecca in the spring of that year. Thither several hundred thousand pilgrims flocked from every part of Turkey and Southern Asia, and large numbers among them, even before reaching their destination, died of cholera. There is no doubt that the disease was carried along with the vast crowd which issued from the region where it is endemic,—the great peninsula of Hindostan,—and by them was disseminated in Arabia and Egypt, whence it advanced along the great highways of travel and commerce into Europe. On the 11th of May the first case occurred in Alexandria, and thence it was carried to Ancona, on the eastern shore of Italy. From Alexandria also it was transported to Constantinople, where it began to prevail July 13. By the end of August it had spread to Malta, Tripoli, Barcelona, and Gibraltar. On the 11th of September it broke out at Marseilles, whence it advanced to Paris on the 25th of the same month; while from Gibraltar it was carried to Southampton, where the first cases of the disease occurred September 27. Seventeen days later it began to appear in London. Finally, on November 2 the steamship Atalanta arrived at Quarantine in the Bay of New York, with fifteen passengers sick with cholera. This vessel was crowded with emigrants from Switzerland and Germany, who had reached Havre by the way of Paris, where cholera then prevailed. The disease did not spread at the Quarantine station nor in the city of New York.

In 1867 the cholera again prevailed in this country. Starting from two points, New York and New Orleans, where it had been introduced from Europe, it followed the lines of travel, and could in many instances be distinctly traced to the movements of persons affected with the disease.

This imperfect sketch will give some idea of the progress of epidemic cholera, and of the devastation committed by it, which falls but little short of that produced by the "*plague*," the "*black death*," and other mortal epidemics. Indeed, its ravages far exceed theirs, if the number of places where the cholera prevailed, and the results of its havoc in all countries, be considered. All other epidemics, except influenza, have been comparatively partial and local in their action: this alone has the world for its arena, and takes its victims throughout the whole human family. So mighty a foe it is that you may be obliged to meet. The experience of the past renders it all but certain that some of you will be called to the performance of this duty; and I therefore shall endeavor to prepare you for the fight, by disclosing the nature, the habits, and the vulnerable points of the enemy, that you may be enabled to exclude it from your neighborhood, or conquer it if it should succeed in entering.

Causes.—The first question which naturally presents itself in entering on the study of the disease relates to the *causes* which produce it. We should first answer the question, What causes do *not* occasion it? Thus, we may be sure that all possible combinations of natural causes, heat and cold, dryness and moisture and electricity, have existed in Europe and America from the beginning; yet they never developed cholera. Neither did any of the more accidental causes, such as famine, or war, the filth, the crowding, or the misery of the poor, the luxury or the voluptuousness of the rich, or the sensuality of all classes. The essential cause of cholera, like the cause of smallpox or of yellow fever, is specific. Yet we may inquire what circumstances favor the generation of the disease, what influences promote the development and propagation of its specific germs or morbid poison.

Heat.—A high temperature is undoubtedly one

of the most efficient among the causes which favor the dissemination of cholera. Its origin in the hot climate of Hindostan, and its general progress, prove this conclusively. In nearly all of the places where there is a great difference between the summer and the winter temperature, the disease has disappeared during the cold season, and attained its greatest intensity during the hot months of the year. In this country, at least, the rule is, I believe, without exception. Like yellow fever and miasmatic fevers, cholera shrinks and vanishes at the touch of frost.

The only apparent exception to this statement is the fact that cholera has prevailed in several cities of Russia during the winter. But this very exception confirms the rule; for in Russia the intense cold of the winter compels the inhabitants to seal their houses by every possible means, while the atmosphere of their interior is kept at a high temperature by huge stoves which render ventilation unusual, if not impossible.

The state of *moisture* or *dryness* of the atmosphere, its electrical condition, the prevalence of certain winds, etc., have been held to be conditions adapted to develop cholera. But none of these influences, taken in their largest sense, have been proved to exert a positive power in generating the disease. All kinds of weather, except the very cold, have been known to coincide with epidemics of cholera.

At the same time, I should mention that in London, and I believe that other places furnish similar illustrations, the mortality was in direct proportion to the lowness of the soil and its proximity to the river. But, when it is recollected that it is in these low and damp districts that the most squalid poverty and the densest population of the English capital exist, too much influence must not be allowed to the atmospheric cause; but, on the contrary, its full weight should be given to the depressing and deleterious action of want, filth, and vice. Wherever the streets are *dark*, *narrow*, and *filthy*, the houses crowded, and the inhabitants ill fed and ill clothed, the mortality of cholera is at least one-half greater than in districts whose inhabitants are surrounded by the comforts of life. In the United States I suspect that the difference between the two classes is even greater. It must be acknowledged that occasional exceptions to this rule have been observed, but not enough to invalidate it, nor to lessen our obligation to cleanse our houses when threatened by a visit from the pestilence; for most frequently it passes by clean and dry places to revel in filth and reek.

Another cause inseparable, almost, from the conditions which have been considered is intemperance in the use of intoxicating drinks. Wherever cholera has prevailed, its easiest victims have been drunkards; and, as the number of these degraded beings is greatest among the very poor and the vicious, the mortality of such classes of persons by cholera has always been excessive. It is unnecessary to cite illustrations in proof of a fact which is notorious and unquestionable. I must not be understood to say that the use of alcoholic drinks during cholera epidemics is necessarily injurious. On the contrary, I believe that such use of them as sober and Christian men may make is rather a preservative against the infection, as well by enabling the stomach to digest food more perfectly, as by promoting a degree of cheerfulness which is by no means the least efficient of the preservatives against the disease. A hopeful and happy disposition is generally thought to be as strong a shield against cholera as despondency and affright are believed to be an invitation to its attacks. It has been said in opposition to this view that the disease has been peculiarly fatal to the inmates of insane hospitals, who are supposed less liable than other persons to panic. But the objection is not valid. Of the insane, a large proportion are monomaniacs, and have at least as lively a sense of danger from an epidemic as other persons. Besides, the feeble bodily health, and the mental despondency of many more, render them peculiarly easy victims to all depressing diseases, and therefore in the last degree to the exhausting attacks of cholera, and indeed of all epidemics.

The quality of the *food* exerts a decided power in determining the attack. The coarse or scanty diet of the poor is no doubt to be added to the other causes already pointed out which operate unfavorably upon this class of society. It has also been observed that that form of diet which occasions attacks of sporadic cholera is most apt to favor the development of the malignant form,—to wit, exclusively vegetable food, particularly in its fresh or uncooked state, unripe fruits of all kinds, everything which is itself acid or tends to become so in the stomach, indigestible substances, such as pork, pickles, and salt provisions generally. The influence of a too exclusively vegetable diet in augmenting the mortality of cholera is perhaps shown by the enormous number of deaths which have occurred among the natives of Hindostan as compared with those among the European population in the same country. But too much importance is not to be attached to this circumstance; for in Ireland, where the use of a vegetable diet is so general, I cannot learn that the mortality from cholera has been unusually great.

The propagation of cholera is, however, due essentially to but one cause: CONTAGION. It must be understood that contagion may be *direct*, as where disease is transmitted immediately from one person to another; or *indirect*, as where the clothing of the sick, their fæcal and other discharges become the media through which the contagious germs are conveyed. Moreover, this indirect contagion may take place through the air that is breathed, or through the water that is swallowed, and therefore through channels which may be quite unsuspected of carrying it.

The question we have to solve is this:—Does cholera, outside of the locality in Hindostan where it originally prevails, give rise to other cases of the disease? If examples of this sort can be produced in any considerable number and perfectly authenticated, the question is decided. One that occurred under my own observation is the following: Years ago a severe and fatal epidemic of

cholera broke out in the Philadelphia Almshouse. The resident physicians were abundantly occupied in the ordinary care of the sick, and five or six young gentlemen were invited to take charge of the cholera patients. These patients were removed from the several parts of the house where they were originally attacked, to a building in the centre of the quadrangle, and were there attended by the physicians from the city who had volunteered their aid. Three or four of these physicians were attacked by cholera, and one of them died. At this time there was no cholera at all in the city, and the young gentlemen had, therefore, no predisposition to the disease. They were attacked while rendering their services to the sick; while the other, or resident, physicians of the house, did not suffer. Now, the only difference between the position of the two sets of physicians was that the one was in constant communication and contact with the cholera patients, and the other was very rarely so. I think, then, the inference is inevitable that the disease was, in this case, communicated from the sick to the well.

Dr. Alison, the eminent professor of Edinburgh, has published still more unequivocal instances, in which persons having left a place where the cholera prevailed for one in which no case of it had occurred, were there seized with the disease, and those in immediate attendance on them were also attacked. Yet the cholera did not extend in these places, and in fact no other cases occurred there at all during the rest of the epidemic. Similar examples have been related of the propagation of the disease in this country.

Other facts demonstrating the contagiousness of cholera may be cited like that at the Philadelphia Almshouse, and even stronger than it. *E.g.*, in 1832 the cases of cholera in Edinburgh were in the proportion of *one* to every *twelve hundred* of the population of the city; while among those in attendance *on the sick* the proportion was as *one in five*. In 1848–9, *one-fourth* of the nurses employed in the cholera hospital took the disease, while in the general hospital, "only a few paces distant," where no cholera patients were received, not a single attendant was attacked.

It has been again and again observed that persons employed to wash the body- and bed-linen of cholera patients have suffered in a much larger proportion than other persons of the same social condition engaged in different occupations. The introduction of the disease by a single ship among a previously healthy population is a fact which has been repeatedly observed. Thus it was that cholera entered Constantinople in 1865. A ship having cholera on board reached that port the first week in July, 1865; thence the disease passed into the hospital, where thirty fatal cases soon occurred; and from the hospital it passed into the city, where it soon became epidemic.

But the disease is communicated by contagion, less evidently indeed, but none the less certainly, whenever the discharges from cholera patients contaminate water which is used by healthy persons for drinking. This has happened again and again. In London there was a certain well into which the contents of a sewer had been percolating for months. Of the water of this well hundreds of persons had been drinking without any obvious injury. At last a case of cholera occurred near by; the dejections were thrown into a privy which communicated with the sewer and indirectly with the well, whereupon more than five hundred persons who received water from that particular well were attacked within three days.

Again, at Constantinople, in 1865, the clothes, mattresses, etc., of cholera patients were washed at a fountain, the basin of which was divided into two parts by a parapet wall; one part was used for washing clothes, and the other for drinking-purposes. Unfortunately, the waste-pipe being broken, the foul water of one side communicated with the clean water of the other, and in one day sixty people died in the small portion of the city which was supplied by the infected stream.

These facts, and countless similar ones, confirm the belief which is suggested by the symptoms of epidemic cholera, their essential identity with those of the sporadic form, and the condition of the alimentary canal after death,—that the material cause of the disease is a poison received into the body by the mouth and stomach, and that the only demonstrable agent in the dissemination of the disease consists of a specific poison contained in the alvine evacuations. It seems difficult to admit that the poison is *atmospheric*,—*i.e.*, inherent in the atmosphere, and not merely absorbed into it from the sick and their excretions; for we are acquainted with no facts whatever which prove the disease to have originated independently of previous cholera patients, or their dejections conveyed by clothing, water, air, or other possible vehicle. Nor has the atmosphere revealed any constituents, or conditions, during cholera epidemics, different from those of the healthiest seasons.

On the contrary, the whole history of cholera shows that it advances from point to point, wherever the *men or things* infected with it are carried; by gradual and short steps on land, as by caravans, or armies, or individual travellers, but with vast strides across seas and oceans, when it is conveyed in ships. Highways and railroads and river-courses mark out its path across continents, because in these the throngs of men are thickest, and continue, like the links of a chain, the long procession of cholera victims which had its beginning in the jungles of Hindostan. Seaports are its favorite halting-places; because in them infected ships and crews congregate. Great cities furnish its most numerous victims; because in them are the very hotbeds in which tens of thousands of human beings are perpetually kept upon the narrow verge which separates disease from health, and where the water, the air, the food, may all readily become contaminated by the germs of the pestilence and spread it through a thousand channels.

This dissemination from man to man, directly or indirectly, is sufficient to account for the spread of cholera; and it is unnecessary to invoke besides, as some persons do, an undemonstrated and occult

condition of the atmosphere which predisposes men strongly to be affected by the emanations from the sick, their excretions and clothing.

We may conclude that cholera is contagious, and that its contagious element is disseminated by whatever can carry a material poison: by bodies of men and by individuals; by ships and by clothing; by winds and by water, by dust and by food; and that the germs of the contagion are contained in the alvine evacuations and in nothing else. The probable nature of those germs we shall have occasion to speak of again.

Symptoms.—The symptoms of cholera are usually divided into three stages: 1. the *forming* stage; 2, the *cold* stage; and 3. the stage of *reaction.* Such a division is natural and proper, because the disease may terminate in any one of these periods: in the first, by an arrest of the attack; in the second, usually by the death of the patient; in the third, by his convalescence.

The forming stage, or stage of *invasion*, may be marked in some cases by a *sudden*, and in others by a *gradual*, development of symptoms. In the former the patient is seized with a general depression of all the faculties of mind and body. The senses are irritable, the head aches and is confused, there is a disinclination to sleep, the limbs totter under the weight of the body, the pulse is frequent and feeble, occasionally fainting takes place, and the skin is cool, and moistened with perspiration. When the attack is more gradual, the earliest symptoms are usually abdominal. Wandering pains are felt in that region; it is distended with flatus, and emits rumbling noises; there is more or less nausea, and a discharge of thin, yellowish, and offensive stools, which gradually grow lighter in color and more frequent. At the same time, the general debility and prostration are remarkably great, and sometimes slight cramps are felt in the limbs. This condition is of variable duration. Sometimes it precedes the full development of the attack by a few hours only; in other cases it lasts for a week or ten days before the graver phase of the disease appears. It is during this stage that the treatment of cholera is most successful: indeed, *it is the only stage in which we can rely upon the effects of remedies.*

The succession of the early symptoms, and the duration of the first stage, are generally such as I have described. But cases now and then occur in which the whole of these phenomena follow one another within the brief space of one or two hours. The patient is stricken down with sudden feebleness, is seized with profuse vomiting and purging and general spasms, and dies without any interruption of the symptoms or any tendency to reaction.

But, more generally, after a greater or less duration of the first stage, the second or cold stage is ushered in by a marked aggravation of all the symptoms. The discharges of fluids from the stomach and bowels grow incessant and more abundant, and vary from ten or twelve to twenty or even more in the twenty-four hours. They are usually passed without effort, and consist of a large quantity of serous liquid, at first somewhat tinged yellow with bile or fæces, but afterwards whitish or grayish, like rice-water, and containing flakes of coagulated fibrin or the *débris* of the intestinal epithelium. In a few instances the stools are tinged with blood.

Vomiting usually coincides with the copious purging. After the food which the stomach may happen to contain is thrown up, large quantities of a whitish or milky-white fluid, exactly like what is discharged from the bowels, are evacuated; more frequently, however, this fluid is at first tinged with bile. It is poured forth, less by the ordinary act of vomiting than by gushes, as if it overflowed from the throat and mouth; and it often escapes from the stomach and bowels at the same instant. Sometimes a distressing hiccup accompanies these symptoms. It is, indeed, but one of the spasms which affect the whole muscular system. They usually commence in the fingers and toes, seize upon the muscles of the calf of the leg, and render the muscular wall of the abdomen as hard as a board. The pain which they produce is extremely severe. At this period the debility is extreme; the patient is unable to rise, or even to move at all, except under the stimulus of the spasmodic pain. The features are shrunken; the nose is sharp and pale and bent to one side. The dusky and sunken eyes, the thin lips, the hollow cheeks, and contracted muscles that stand out like cords under the tight and clammy skin, present a physiognomy such as belongs to no other disease. The hands and feet grow cold, and steadily the coldness creeps upward towards the trunk; the integuments of these parts are shrivelled and damp, as if they had been long macerated in water; and, if they are pinched up, the fold of the skin remains for some time. The eyes grow dull and dry, the tongue has a pasty or sticky feel, the urine is almost suppressed. As the attack advances, the patients fall into a dull, listless, and motionless state, which must not be mistaken for insensibility, but which arises from complete muscular exhaustion and a want of energy in the cerebral and spinal functions. They express no interest in anything, and hardly notice the attentions or the distress of their friends. Yet they will generally give clear though languid answers to questions, and fall again into their inert and unobservant state.

As these symptoms advance, as the fluids of the body are wasted away, the blood accumulates and stagnates in the veins, and gives to the hands and feet, the nose and lips and other features, to the neck, and even to the entire surface of the body, a bluish, leaden, or violet tinge, precisely like that of cyanotic children. The pulse, which was already weak and thready, ceases to be perceptible; the carotids, even, can no longer be felt; then the impulse of the heart ceases, and its first sound becomes inaudible. The skin is everywhere cold, is sometimes of an icy coldness, and yet the patients seldom complain that it is so. Even the breath as it issues from the nostrils is cold.

The blood no longer circulates, and the heart is still. If a vein is opened, a few drops of black and viscid fluid trickle from the wound, and, if they coagulate, yield but little serum, and, in place of a clot, nothing but a diffluent jelly. The voice falls to a mere whisper, or is quite extinct. The features

assume a horrid aspect: the temples and the cheeks are hollowed; the nose is pointed, and the nostrils are obstructed with dry powdery crusts; the eyes are dry, dull, and sunken behind the half-closed and purple lids; the conjunctiva is no longer moistened by its secretion, and grows bloodshot; the temperature of the mouth may fall to 79° or 80°; a viscid exhalation bedews the icy and marbled skin; and the whole body is so shrunken from its natural proportions as to lose all marks by which its identity may be usually recognized. From this pulseless, cyanotic, cold, and exhausted condition there can be but one step to death. It generally comes on gradually, the patient sinking into complete insensibility; in other cases he expires suddenly upon making some unusual effort.

Reaction.—At any period of the progress which has been described, the contest between the system and the disease may be decided in favor of the former. If this takes place in the early stage, before there is any blueness of the skin or any very profuse evacuations, the recovery may be gradual and without remarkable phenomena. The pulse regains, more or less, its natural force; the skin grows warm again, first upon the trunk and afterwards upon the extremities; the breathing becomes easy, and, the diarrhœa having already ceased, convalescence is established. But in proportion to the violence of the symptoms, the intensity and duration of the cold stage, the cramps, and the evacuations, will be the tendency to an opposite extreme upon recovery, a tendency to febrile reaction, accompanied with more or less congestion of internal organs. The first sign of improvement is the subsidence of the evacuations, of the vomiting, and then of the purging, or, if the diarrhœa continues, it loses the characteristic appearances of cholera, and is more or less brown; the next step is the diminished coldness of the extremities; then the improvement of the pulse; and finally the restoration of the strength. Or, if the attack has been severe, particularly if the algid stage has been prolonged, fever of a low form is set up, which, indeed, may ultimately terminate in death. It is marked by dryness of the tongue, a brown crust upon the teeth and gums, jerking of the tendons, delirium, and coma; in one word, it is a typhoid state. Sometimes these symptoms are evidences only of exhaustion and of the inability of the system to resume its normal action; in other cases they appear to be due to a local inflammation of low grade established generally in the lungs, and which is usually latent. In other cases, again, the nervous system bears the brunt of the reactionary effort, and the patient is attacked by convulsions or perishes in an apoplectic fit. These phenomena appear to be due in most instances, if not in all, to renal obstruction, by which the effete matters of the system which should be excreted by the kidneys are retained in the blood, and the phenomena, as a whole, may be termed uræmic. In other cases a wasting diarrhœa, due probably to the damaged state of the intestinal mucous membrane, is superadded to the already existing typhoid state. Occasionally the parotid glands become enlarged and painful, and sometimes a measly or roseolous eruption appears upon the skin.

It frequently happens that convalescence is slow and irregular. The system seems shattered by the trial it has passed through; the nervous susceptibility remains morbid for a long time, or, what is still more usual, the function of digestion is greatly impaired. The appetite is capricious and the digestion feeble. The mouth is pasty, the abdomen tympanitic, the bowels are irregular and alternately confined and relaxed. Finally, patients who leave their bed too soon, or indulge prematurely in their ordinary diet, are liable to relapse, perhaps fatally, into the original disease. In fact, it has occasionally happened that such a relapse has taken place several days after an apparent restoration to perfect health.

Anatomical Characters.—In cholera, as in most other diseases, the pathological condition of the organs does little more than explain the *effects* of the disease properly so called: it reveals the mechanism by which the secret and inscrutable essence of the disease produces its ultimate effects, but it throws very little light upon the nature of that essence or efficient cause. But at the same time it leads to a probable conjecture of the primary element in the derangement of the organism, and explains in part, at least, the mode in which remedies which have been found successful in the treatment exert their salutary powers. I shall not attempt to present a detailed and minute account of this chapter in pathological anatomy, but shall draw attention only to its more important divisions.

And, first, of the *blood*. The grosser physical characters of cholera blood, as found after death, are these: As a general rule, the arteries are nearly empty; they sometimes, however, contain a small quantity of black and viscid blood. The veins and the right side of the heart are filled with dark blood, which is in general very imperfectly coagulated, and often fluid; even when clots are formed they are for the most part soft, and resemble blackberry jelly. The veins of the brain are usually gorged with liquid and black blood, and the same is true of the veins of the small intestines. The red globules themselves undergo important changes. They have lost their watery constituents and become shrivelled and irregular in shape, and may even be completely disintegrated. Such is the usual state of the circulating fluid; but some observers have found firm clots within the heart, more or less deprived of coloring-matter, forming true fibrinous coagula. Still, this condition is undoubtedly of infrequent occurrence.

Similar changes are found in the blood drawn during life. Owing to the loss of water, the proportion of its solid ingredients is relatively increased, so that a given bulk of it weighs more than an equal quantity of healthy blood. In other words, its specific gravity is increased. Thus, the maximum specific gravity of healthy blood is 1060, while that of cholera blood is 1080. The serum of the blood becomes denser than natural, and rises from 1028 to 1040. In like manner, when we come to examine the solid constituents of this fluid we find the proportion of

them all increased. The proportion of red globules rises from 140 to 170 parts in 1000. The fibrin, although its relative quantity does not increase, appears to have undergone important changes, for it coagulates with difficulty or not at all. The albumen, of which the normal proportion is 70, generally falls, and has been found as low as 49 (Becquerel and Rodier), a portion of it having been lost by percolation through the intestinal mucous membrane and by secretion through the kidneys. On the other hand, the fatty and extractive matters, like the globules and fibrin, are augmented, and in even a larger proportion. For normally they average ten parts in a thousand of the blood; but in cholera they rise to twenty, thirty, and almost to forty parts in a thousand. This remarkable circumstance has been attributed to the absorption of the adipose tissue, which is so general and so rapid in this affection. We shall presently see that this fatty matter is poured out through the intestinal tube. In connection with the state of the blood, a singular fact relating to the *temperature* of the body before and after death may here be noticed. In the algid stage all the external portions of the body are unnaturally cold, while the interior, as indicated by the temperature of the vagina and rectum, is above the normal grade; precisely as happens during the cold stage of the algid form of malarial fevers. In those patients who die during the collapse, and very cold, as was before remarked, the temperature of the surface rises one, two, or three degrees in the course of an hour or two; and the body is much longer in cooling than usual. Sometimes, indeed, the friends of the patient are led to hope that life is not altogether extinct. Another circumstance is apt to encourage this hope, or to inspire the ignorant with a mysterious horror. It is the *muscular contractions* observed in various parts of the body. They "vary in extent from flickering and tremulous undulations in a few fibres, scarcely to be seen or felt, to contractions sufficiently powerful to move the limbs from their position or even to displace the body itself." They begin shortly before death, and last a variable time, from a few minutes to two hours. Similar phenomena have been observed in other diseases, and especially in yellow fever.

On opening the *abdominal cavity*, one is struck by the general pink or rose tint of the peritoneal coat of the intestines. It is produced by a hyperæmia of the portal venous system; sometimes the color is very dark, the venous trunks being full of pitchy blood. The serous surface is drier than usual, and often has a sticky feel, from a layer of tenacious glutinous matter, which forms a lather when rubbed between the fingers. This shows it to be albuminous.

The dryness of the peritoneum is a type of the condition of all the tissues, of the meninges, the pleura, the pericardium, the brain, the lungs, the muscles, and the glands.

The *contents* of the intestinal canal vary somewhat in its different portions. In the *stomach* the liquid is generally thin, transparent, greenish or grayish, and occasionally has a tinge of deep red. It sometimes contains portions of coagulated mucus, resembling shreds of boiled rice, and also an unctuous substance which adheres to the walls of the organ and is thought to be modified albumen. Fatty globules have been observed floating in the gastric liquid, as they have also been in the stools and in the urine during life, as well as in the vomit of cholera.

The same serous fluid is found in the *small intestine*, but its color becomes a deeper red, almost of a chocolate shade, in the ileum. At the upper part of the bowel it is thicker than below; indeed, it seems at every step to be diluted by a fresh secretion of liquid from the mucous membrane. The epithelial shreds and patches are more abundant here than in the stomach, and along with them is also found the albuminous matter already described, deposited in a thin layer upon the surface of the bowel. In the *large intestine* the contents do not differ materially from those last described. In some cases the intestinal liquids, "when exposed to a temperature of 212° F., coagulate like the serum of the blood, and yield a similar odor, thus exhibiting the presence of a large amount of albumen." Some observers have failed to observe this effect,—partly, it may be suspected, because they neglected the necessary precaution of rendering the fluid, which is generally alkaline, acid before exposing it to heat; for unless this be done no coagulation will take place. The albumen, too, is often altered in its physical characters, and requires to be boiled with nitric acid before coagulating. The brown or chocolate color of the liquid in the small intestine which is sometimes observed, and which I have already referred to, is due to the presence of the coloring-matter of the blood derived from broken-down, and occasionally to the presence of unaltered, red corpuscles.

The *mucous membrane of the stomach* seldom presents any organic changes. Its tissue is swollen by the infiltration of serum. Its color is usually unnatural; sometimes pale, but more frequently of a rosy or of a purplish red, like certain onion-skins, or else of a dark brownish-red color, which is due to the congestion of the veins in the sub-mucous cellular tissue. When the color is light, hyperæmia is its principal cause; but when it is dark, congestion of the larger trunks and ecchymosis exist. Occasionally this membrane is reduced to the condition of a mere pulp. The same varieties of color are found in the *small intestine*, increasing gradually in depth from the duodenum to the cœcum, being most marked in the lower portion of the ileum, in consequence of the sub-mucous extravasation of blood at this point. Here, as in the stomach, the diffused and brighter redness is found to be due to extreme capillary congestion. But much more important changes are revealed by a microscopic examination. As long ago as the first American epidemic of cholera (1832–35), Prof. Horner, of the University of Pennsylvania, described an exfoliation of the epithelial lining of the alimentary canal, whereby the extremities of the venous system are denuded, as characteristic of cholera alone. And in 1849 Prof. Jackson, Emeritus Professor of the In-

stitutes of Medicine in the University, and Dr. John Neill, then Demonstrator of Anatomy in that institution, in conjunction with the late Dr. William Pepper, and with the late Dr. Goddard, who was also at one time Demonstrator of Anatomy in the University, presented a report to the College of Physicians, in which they, too, showed that "the epithelial layer of the intestinal mucous membrane was either entirely removed, or was detached, adhering loosely." I claim for the University the credit of having made this discovery, whatever may be its value, long before it was announced in Europe. Indeed, it was only in 1860 that the eminent pathologist and microscopist Dr. Beale, of London, arrived at the same conclusion. He says of the rice-water contents of the intestines, "This has been proved to consist almost entirely of columnar epithelium; and in very many cases large flakes can be found, consisting of uninjured epithelial sheaths of the villi. . . . In bad cases it is probable that almost every villus, from the pylorus to the ileo-cœcal valve, has been stripped of its coating during life." The capillary veins being also greatly distended, it is evident that there is no barrier to the transudation of the fluid portion of the blood into the intestine; while an almost insuperable one exists to any absorption from the bowel. The solitary glands are almost always distinct, their prominence and general increase of size being, for the most part, due to the œdematous state of the tissue in which they are contained, but partly also to the presence of a substance which appears to be albumen. The patches of Peyer do not undergo any real alteration, but, like the solitary glands, are swollen by an imbibition of serum. The mesenteric glands are slightly enlarged, and to some extent infiltrated with "a whitish, granular exudation" (Virchow), of undetermined nature, but probably albuminous.

In the *large intestine* are found the same changes of color and consistence of the mucous and submucous membrane as at the upper portion of the intestinal canal, but with much less frequency. The isolated follicles of this, as well as of the upper division of the bowel, are generally prominent, and sometimes extremely numerous.

Neither the *spleen* nor the *liver* presents any special alteration. The *gall-bladder* is generally distended with glairy bile. The *kidneys* are often congested, and the calices contain a large quantity of epithelial scales, which give the urine a turbid appearance in the bladder. The urine is albuminous, as it is found to be in the early stage of the disease. The *lungs* present no other lesions than result from hypostatic congestion; and the *pleuræ*, like the peritoneum, have sometimes a sticky feel. The *heart* offers no uniform alteration. The *brain*, too, is unchanged; but the pia mater is infiltrated with serum, which is also abundant in the lateral ventricles; and the cerebral veins are gorged with black blood.

Such is a succinct account of the most important pathological changes in the organism which are produced by cholera. And, now, do they throw any light upon the mechanism of the disease? That its primary cause is material, and acts upon the gastro-intestinal mucous membrane and upon the organic nervous system, we cannot doubt. The whole history of its epidemic progress proves this to be the case, as well as the lesions found after death. Unlike other epidemic diseases, such as typhus, yellow fever, the plague, etc., we can find no primary alteration of the blood in it, which will throw light upon the succession of the symptoms. These, on the contrary, point to the gastro-intestinal canal as the material starting-point of the morbid processes which develop the phenomena of cholera. All of the phenomena of the complete attack point in the same direction. Most of them succeed upon a profuse flow of the serous and watery portions of this fluid into the bowels. This it is that produces the vomiting and purging; this prostrates the patient, and wastes away, in a few hours, the fullest and firmest form; this chills the extremities and afterwards the trunk; this thickens the blood, so that the capillary vessels refuse any longer to convey it, and spreads its cyanotic shadow over the whole surface of the body; this cuts off the supply of blood from the heart; this paralyzes the nervous system, organic as well as animal; this obstructs the kidneys and arrests their secretion; and this, therefore, acting through the various links of the pathological chain, *is the cause of death.*

But what is the remoter cause of cholera? What sets in motion these successive wheels which end in crushing out the life of the cholera victim? Evidently, something received from without and swallowed. One opinion is that it consists of certain microscopic fungi, or their germs, which, on being received into the bowels, propagate their kind and destroy the epithelium. It is believed by some that this fungus takes its origin on the banks of the Ganges, and that it is produced upon the rice-plant. Having once originated the disease, its germs contained in cholera dejections, being mixed with water or borne upon the wind, enter the system of new victims, who, in their turn, disseminate the plague. Another theory is (Richardson) that, "as pus undergoes changes which convert it into a septic poison, so the excreted matter from the alimentary canal is equally capable, under peculiar conditions of oxidation, of producing an alkaloidal organic poison, which, soluble in water, but admitting of deposit on desiccation," becomes the agent for the dissemination of the disease. The former is the more generally accepted opinion, and seems to be supported by many facts; but the latter has numerous supporters and many facts also in its favor. Opposed to the latter theory, however, stands the insuperable objection that outside of Hindostan epidemic cholera never did and never does arise spontaneously, but can always be traced to its source in that country. Consequently, there must be in the disease a certain specific something, —whether a cryptogam or not is of subordinate importance,—an essential material, capable of propagating itself in the alimentary canal of human beings, of exciting there certain definite lesions and symptoms, and of communicating to the alvine discharges the property of occasioning the disease anew.

In what does sporadic cholera differ from malig-

nant epidemic cholera? Only in its cause and its degree. Its mechanism is the same. Yet sporadic cholera is a disease of the stomach and bowels usually produced by the direct application of irritants to their surface. This no one doubts. Wherefore it seems but rational to conclude that epidemic cholera is also an intestinal disease, which differs from the sporadic form chiefly by the intensity of its cause, the gravity of its symptoms, and the nature of the special cause which produces it.

(To be continued.)

ORIGINAL COMMUNICATIONS.

SULPHURIC ACID AS A PROPHYLACTIC IN CHOLERA.

BY ROLAND G. CURTIN, M.D.

THE long-looked for and much-dreaded visitor—the Asiatic cholera—seems to be prepared to spread its dark pall over our land. It is now approaching us by its well-beaten paths in Europe, and also by way of the lower part of the Mississippi Valley, where the poison is nursed by the higher temperature which favors its propagation. In another month it will probably be in our midst, seeking for victims to satiate its rapacious appetite. It therefore behooves us to be prepared for it. How shall this be done? From past experience in other epidemic diseases that have been effaced or robbed of their sting, it would seem that we must look for succor in prevention rather than in cure. It is my intention to give to the profession some experience which I hope may prove to be of value in regard to the prevention of the disease.

Our country was first visited by this unwelcome guest in 1832, next in 1848 and 1849, again in 1853 and 1854, and the last time in 1865 and 1866. During this last visitation I was resident-physician in the Insane Department of the Philadelphia Hospital. The disease had almost entirely disappeared from the city and from all parts of the Philadelphia Almshouse and Hospital, except from the women's wards in the insane department, where it still continued in a very virulent form. Strange to say, it was almost entirely confined to three of the seven wards on the female side of the hospital. It was so persistent that the Board of Health paid the hospital an official visit, but were unable to account for the presence of the disease in particular wards. It is true that the women's apartments were very much crowded, there being three hundred and fifty inmates, but the wards in which it was so prevalent had proportionately fewer inmates than others which almost entirely escaped. During the whole epidemic only two cases occurred in the male wards, while among the females one in every nine was attacked. Sex would not account for this difference, for statistics at large show that male and female lunatics are equally liable to the disease.

I was induced to try sulphuric acid by my friend Dr. James F. Wilson, with gratifying results, if I may be allowed to judge. Dr. Wilson had read an article in a British newspaper in which the writer stated that the workmen and their families connected with a large factory had been treated with sulphuric acid as a prophylactic during an epidemic of cholera. The correspondent stated in the letter that "the result was that not one man or any of their families were attacked with diarrhœa, whilst around them death took its own course." I caught as a drowning man at this straw, for everything else had been tried and yet the disease continued its ravages. After having concluded to use the sulphuric acid, the next thing was to administer it to all the patients, many of whom were so suspicious that they refused at all times to take medicine, for fear of being poisoned. Knowing that it would be impossible to conceal it in their food or usual drinks, I concluded to administer it disguised as lemonade, and announced through the nurses to the patients that I intended to "treat" the whole institution to lemonade every day, which announcement was well received in general, and by some of them with enthusiasm. The drink was made in this way. About twenty drops of the dilute sulphuric acid were mixed with four ounces of water and sweetened with white sugar. Some oil of lemon and a few cut lemons greatly assisted in the disguise. What followed the administration of the sulphuric acid can best be shown by the notes taken at the time. The diary was begun on August 20, 1866, before which time seventeen cases had occurred in the insane department.

August 20.—Four new cases.
August 21.—Four new cases.
August 22.—Four new cases.
August 23.—Two new cases. Board of Health visited the hospital.
August 24.—Five new cases.
August 25.—One new case. Acid given for the first time, in the afternoon.
August 26.—Four new cases *during the night*, within twelve hours after the first administration of the acid.
August 27.—No new cases.
August 28.—One new case,—a woman who refused to take the acid.
August 29.—No new cases.
August 30.—No new cases.
August 31.—No new cases. The acid was discontinued.
September 1.—No new cases.
September 2.—Two new cases,—two days after the suspension of the acid.
September 3.—No new cases. Acid resumed.

The acid was continued for some time, and no more cases occurred.

It will be seen by the above diary that up to the time of administering sulphuric acid the disease was pursuing a steady course in the female department. It is true, and should be here stated, that every means had been tried to banish the disease, such as ventilating and cleansing the wards, spreading disinfectants, scattering the patients by using the large sewing-room for a sleeping-ward, attention to diet, etc., but without apparent effect. The acid was first given on the 25th of August and continued until the 31st. Four cases occurred *within*

twelve hours of the time when the acid was first given. After this only one case occurred while the acid was being used, viz., on the 28th. This was a poor ignorant (?) lunatic, who, upon tasting it, spit it out, and surprised me very much by saying, with great vehemence, "Docther, ye call this limonade; but ye can't desave me; it's nothing but ile of vitriol." On the 31st of August it will be seen that the "lemonade" was stopped, on account of the exhaustion of the supply of white sugar in the drug-store, as without this sugar it would have been impossible to prepare the acid in such a manner as to insure the patients' taking it. On the 2d of September, *two days after the suspension of the use of the acid, two new cases occurred*, both of which proved fatal. The prophylactic was then resumed, and *no new cases* afterwards occurred in the insane department; but cases continued to arrive from the city until the 1st of November. The use of the acid was continued uninterruptedly for several weeks. My friend Dr. J. F. Wilson gave it to the patients in the surgical wards during the epidemic, and he informs me that the *cholera visited every department of the almshouse and hospital except the surgical wards.*

The question naturally arises, was it the sulphuric acid that arrested the march of the disease? I think it was, for the following reasons:

1. *The prompt disappearance of the disease within twelve hours of the time when the acid was first administered*, the only case arising during its use being that of a patient who refused to receive it. The acid was stopped on the 31st of August, and two days after this two cases occurred. The acid was then immediately resumed, and not a single case occurred afterwards.

2. *The fatality attending the disease.* When an epidemic declines from natural causes, it generally becomes less fatal. Of the four patients attacked on the 26th of August, three died, of whom one was a young, robust epileptic, who lived but five hours after the first symptom; another was a strong lunatic, who succumbed in nine hours. The two cases which occurred on the 2d of September, after the suspension of the use of the acid, both died; thus showing that the type was none the less fatal.

How did the sulphuric acid act? According to Dr. G. B. Wood, it has the following effects upon the system, viz., *tonic*, *astringent*, *refrigerant*, and diuretic. It has been largely used in the treatment of the first and second stages of cholera. Dr. Macnamara, in his work on Asiatic cholera, recommends the use of dilute sulphuric acid, in doses of fifteen minims, in the second stage. The celebrated "Austrian Specific" was composed of sulphuric and nitric acid. Nitric acid had been used in India in the treatment of cholera with considerable success. It was tried in England and found to be of no avail, when further investigation proved that the nitric acid of India contained a considerable amount of sulphuric acid. The latter was an accidental product of the manufacture of the nitric acid of India. Hence the use of the combination of these two acids in the treatment of cholera. Elixir Halleri, or liquor acidi Halleri, has been much used in India, and is ordered as part of the medical stores of the British army there. It consists of sulphuric acid and alcohol. Drs. Buxton, Sansom, and Fuller, of England, used sulphuric acid with success in the first stages of cholera, especially in the choleraic diarrhœa. From the above statements it would appear that sulphuric acid itself has some effect upon the disease; and now we will proceed to discuss its influence as a prophylactic.

It had been noticed that workers in copper were remarkably exempt from cholera, and upon investigation it was found that the air surrounding them was considerably charged with sulphurous acid, which gave rise to the supposition that this was the active preventive agent. This led to the use of sulphurous acid in cholera districts and hospitals, but with what results I have not been able to learn.

Dr. Burg, in reviewing the statistics of deaths from cholera, found that "out of thirty-two thousand artisans in copper, brass, and bronze, employed in Paris and other cities, during the last outbreak of cholera, only sixteen deaths resulted from that disease. Another interesting fact bearing on this question is that the city of Rio Tinto, surrounded as it is by copper-mines, has never been visited by this epidemic."

The sulphurous acid found near these mines proceeds from the smelting-works, in which the sulphurets of copper are generally used; other sulphurets often, being associated with the copper ore, also yield their sulphur to the atmosphere. Still further, it has been noticed that persons living near gas-works are less liable to be attacked than those living remote. Here also we find the atmosphere more or less impregnated with sulphurous gases. Almost all gas coal contains sulphur; and the process of purification in part consists in the removal of the sulphuretted hydrogen. Hence we discover a source of sulphurous gases, which gases may be the protecting agents. It may be, judging from these circumstances, that the cholera-germ is destroyed; for in the case of Rio Tinto, which is surrounded by sulphurous acid, it would seem to form an impenetrable barrier to the cholera. It is a well-known fact that sulphurous acid in the form of a sulphite will arrest fermentation; and it has been suggested that it acts in the same manner upon the zymotic cause of cholera.

But, again, we find that sulphuric acid seems to have an influence over the disease, which would lead us to ask whether the *sulphur may not be the destroying agent of the cholera-germ*, acting as a specific in the same manner that it does in the case of the itch insect. If this be true, the disease may be easily eradicated from a ship or a house or any infected locality by fumigating with sulphurous acid,—simply by burning sulphur; also disinfecting privy-wells and other objectionable places by means of sulphate of iron, and at the same time giving liquid sulphurous acid, sulphuric acid, and the sulphites, by the mouth, to those exposed.

It has already been stated that sulphuric acid may act beneficially independent of any specific action upon the cholera-germ.

I have said that it is a tonic, astringent, re-

frigerant, and diuretic. The vital energies are often very much reduced, digestion is poor, and the intestines and the system at large are in a relaxed condition, the result of the high temperature of summer. Here we find the condition favorable to an attack of cholera. The tonic, astringent, and refrigerant effects of the sulphuric acid would all be eminently indicated by these conditions, and its administration might tide the patient over the period of danger. It may also act beneficially in another way. We all know the depressing effect of fear, which undoubtedly predisposes to cholera. A prophylactic given in such cases would allay the fear and thus ward off the disease. But this latter condition was not a characteristic of the poor lunatics in the Philadelphia Hospital; for many of them knew no fear except that produced by their hallucinations. It is pleasant to have a preventive at hand; but in none of the text-books have I been able to find anything recommended as such in cholera. Having one, we might be able to quiet the fears of the nervous and keep them from the often injurious nostrums of those who prey upon this class.

One thing should be remembered. It is this, that sulphuric acid, when administered for a long time continuously or in too large doses, may give rise to symptoms of intestinal irritation. However, although the acid was given to the lunatics uninterruptedly for several weeks, no ill effects were observed. It should be given only to those who are greatly exposed during an epidemic of cholera; otherwise the above unpleasant effects may be produced.

332 South Seventeenth Street, Philadelphia.

A SUGGESTION FOR THE TREATMENT OF APPROACHING COLLAPSE IN CHOLERA.

BY WILLIAM PEPPER, M.D.,

Lecturer on Clinical Medicine at the University of Pennsylvania.

IT is with no intention of discussing at length the causes, pathology, or treatment of cholera that this brief practical article is penned. The investigations into the precise nature of the cholera-poison cannot yet claim to have attained definite and complete results. Nor can it be asserted that any of the various explanations of its *modus operandi*, however ingenious and plausible, affords full and unquestionable satisfaction.

That which is, however, well known and generally accepted in regard to the mode of action of this fatal poison, is fortunately of material value for practical purposes. It may be concluded, at least, that the peculiar symptoms of true cholera depend upon the presence in the economy of a specific virus, introduced often by the drinking-water, though probably also by other avenues, which produces a wide-spread, peculiar irritation of the gastro-intestinal mucous membrane (and probably of associated secreting glands), attended with rapid epithelial proliferation, usually with profuse serous discharges; a special morbid state of the great ganglia of the sympathetic nerve; and serious changes in the blood-mass. I do not even raise the question (for the precise settlement of which I do not think the data yet exist) as to which of these may be the primary change: whether, in other words, the specific gastro-enteritis is the primary essential condition, and the morbid excitation of the sympathetic nerve, and the blood-changes, secondary and subordinate steps; or whether the alterations of this fluid are the initial phenomena, due to the presence of a poison having a special action upon the sympathetic ganglia, and the gastro-intestinal irritation and the profuse sero-epithelial discharges the result of an effort to excrete this poison; or whether, finally, the virus acts directly and primarily upon the great sympathetic nerve-centres, and the gastro-intestinal changes, the peculiar discharges, the alterations in the blood, and the attendant general symptoms, are consequent upon violently disturbed function.

The symptoms of true cholera,—the formative stage of mere intestinal irritation, cholerine, so called; the stage of characteristic sero-epithelial discharge, with its symptoms of intense gastro-intestinal and reflex muscular irritation; the stage of collapse, with its wide-spread and profound disturbances of respiration, circulation, calorifaction, and secretion; these are too well known from the exquisite classical descriptions to need repetition. My own belief with reference to the mode of their production is, that while the primary essential condition consists in the extensive and severe irritation of the gastro-intestinal mucous membrane, a very large and important share in the causation of the discharges and the consequent alterations of the blood, and especially of the symptoms of collapse,—the failure of the cutaneous circulation, the condition of the respiration and action of the heart, the arrest of secretions,—must be attributed to the direct or indirect implication of the abdominal and thoracic sympathetic ganglia. There is nothing original in this view of the vastly important *rôle* played by the sympathetic nerve in the production of the symptoms of collapse,—whether in cholera or other conditions which may closely simulate this phase of that disease, as acute intestinal obstruction or poisoning by some acrid substances. Want of space forbids me to amplify it now. I will merely remark that there seems no reason to doubt that while the direct, continued, and intense irritation of the gastro-intestinal fibres of the abdominal sympathetic might well paralyze them and cause paralytic dilatation of the gastro-intestinal capillaries with free discharges of serum, there might be a wide-spread irritation of less intense degree of the other branches of the abdominal and also of the thoracic sympathetic, producing the arrest of circulation and secretion, the slowing of the heart, and the disturbance of respiration, which contribute to form the stage of collapse.

Certainly for practical purposes we must recognize the presence of the three elements of gastro-enteritis, of irritation of the sympathetic nerve, and of serious blood-lesion. During the formative stage of the disease and the early part of the second stage, the first of these elements is predominant; later,

the evidences of the other two make their appearance and herald the approach of its concluding and gravest phase. The indications for treatment are to be found in the above considerations. The supreme importance of the prompt treatment of cholerine, or of any and every evidence of gastro-intestinal irritation occurring during the prevalence of cholera, is well recognized; and the rules for its relief, by rigid diet, absolute rest, and the moderate use of opium and sedative astringents, are generally accepted. The conflicting theories of the *modus operandi* of the cholera-poison have led to confusion in regard to the management of the stage of discharge; and mischievous results have followed the application of some of the specific plans for its treatment based upon peculiar views of the significance of this symptom. Not one of these specific plans appears to merit approval. Those who have seen most of this dread disease seem most inclined to rational modes of treatment based upon sound general principles.

Among the most important of the general rules for the management of this stage of discharge, may be mentioned, the enforcement of absolute rest in the horizontal position, in a cool, well-ventilated, and disinfected room; the administration of small quantities of bland nourishing food at comparatively short intervals; the administration of fluid, even if portions of it are speedily rejected; the effort to maintain heat and circulation by external applications; the avoidance of stimuli, save in very minute quantities, freely diluted; the moderation of the discharges and the relief of the painful cramps by such remedies as the mistura medica, or chlorodyne; and the use of full doses of such drugs as bismuth, for the benefit of its local sedative and astringent action. Frequently, however, despite the most judicious and prompt treatment of this stage, the disease hastens on towards the condition of collapse. The discharges may, to a great extent, have ceased; but the alterations of the blood and the implication of the nervous system have advanced too far, and unmistakable evidences of collapse make their appearance. The most varied and contradictory plans have been suggested for the relief of this alarming state and the prevention of the deeper and hopeless degrees of collapse. The object of this little article is to suggest another plan, which it was my intention to have used had any cases of cholera come under my care this summer, and which I have now hastily written out, being at a long distance from home and from the present seats of the epidemic, thinking it might merit a trial. The demand in this state of approaching collapse, in addition to a continuance of the measures suited to the previous stage, is for some means of producing reaction and restoring to the blood its fluidity and properties which fit it for circulation. The effects of such measures as cold affusion or venesection are evidently but temporary and palliative, and do nothing towards the actual relief of the blood-lesion. Towards this end, the use of injections of warm saline solutions into the veins seems to contribute more directly than any other measure; and in the late epidemics of cholera abroad, such injections have been employed with considerable success. They aid in restoring to the blood its bulk, fluidity, and saline property, and certainly produce in many cases a remarkable re-establishment of circulation. I can see no reason why the saline ingredient employed should not be dissolved in a dilute albuminous solution, so as to combine some nutritive value with the above-mentioned properties.

Being impressed with the large share taken by irritation of the sympathetic nerve in the production of the symptoms of collapse, and remembering the wonderful controlling influence exercised over some morbid states due to similar irritation (I refer chiefly to convulsion, whether epileptic or symptomatic) by large doses of the bromide of potassium, it has occurred to me that this drug might be of service in the stage of cholera we are considering; and, as it is impossible to secure the introduction of a sufficient amount by the mouth or enema, that it should be given by injection into the veins (grs. xlv in f℥iij water, repeated at intervals of twenty minutes). Such a measure would probably secure the advantages of injections of other saline substances, and in addition it would enable this remedy to exert its full power over the state of irritation of the sympathetic nerve, which it so wonderfully controls under some other conditions.

I had intended, if any cases of cholera in this dangerous and too often fatal stage had presented themselves to me for treatment, to have fairly tried the use of *large* doses of bromide of potassium, given by injections, of such strength and in such quantities as experience has shown safe in regard to other salines.

COMPOSITION OF VALENTINE'S PREPARATION OF MEAT-JUICE.—BY WILLIAM H. TAYLOR, STATE ASSAYER, VIRGINIA.

Water		61.12
Organic substances		27.90
Containing uncoagulated albumen	1.11	
Fat	.13	
Creatin, creatinin, and other organic constituents of flesh-juice and blood	26.66	
Inorganic substances		10.98
Containing chloride of sodium	1.42	
Sulphate of potash	.52	
Phosphates of iron, lime, and magnesia	1.21	
Phosphates of potash and soda	7.83	

—*Virginia Clinical Record.*

TREATMENT OF CHRONIC DISEASES OF THE BLADDER WITH INJECTIONS OF HEALTHY URINE (*Lancet*, May 10, 1873).—Dr. T. Clemens proposes injections of fresh and healthy urine in the treatment of old disorders of the bladder, such as catarrh, chronic inflammation, gravel, etc. A young and well-fed individual should be made to micturate directly and slowly into a syringe which has been warmed to 90° Fahr., and the urine should then be injected into the bladder, previously emptied and washed out with tepid water. This should be done twice or thrice daily. He has obtained good results in this way after having failed in the use of all known remedies.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 12, 1873.

EDITORIAL.

IN the mortality list of our issue of July 5 there is reported a death from sporadic cholera. Thinking it might interest our readers, we have written to Dr. W. H. H. Githens, and obtained the following report of the first case, closely resembling cholera, occurring in our city this summer:

"June 26, 1873.

"TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

"Edward McN., a sober, industrious shoemaker, working at home, was somewhat depressed by the loss of a child, and the next day was himself taken sick with purging, vomiting, and cramps in the stomach and legs. The stools were liquid fæcal matters at first. His wife gave him boiled milk and water to drink, and the subsequent passages consisted of diluted milk, with little or no change of color (alkaline in reaction). The matters vomited had the same appearance, and were not bitter.

"The next morning, on being summoned, I found the patient partially collapsed. I immediately administered morphia sulphate—gr. ¼—hypodermically, and prescribed a mixture containing bismuth and morphia, to be taken at short intervals, with aromatic sulphuric acid to be added to the water which I allowed him to drink as soon as the morphia had quieted his stomach. There was no recurrence of either the purging, vomiting, or cramps after my first visit, but the skin did not return to a healthy condition. It remained cold (thermometer not used), cyanosed, shrivelled, and bathed in a profuse perspiration. The suppression of urine, which had been but partial before the use of the morphia, became complete afterwards; the voice remained whispering; the pulse soon became imperceptible at the wrists, and he died about sixty hours after the commencement of the attack.

"Shall we call this a case of cholera? There was no recognized source of contagion. The man and his wife and two children lived, worked, ate, and slept in one small apartment in the second story of a house in the most crowded section of the city. The room had windows on the north side only. The whole house was pervaded with a horrible odor from a privy-well immediately beneath it, and not provided with any chance of ventilation or any sewer connection.

"But these conditions, although favorable to the spread of cholera, are not recognized as being sufficient in themselves to originate it. On the other hand, we had all the symptoms of cholera,—watery discharges, free from odor, vomiting without bile, cramps in the stomach and limbs, suppression of the urine, loss of voice, intense thirst, great depression of temperature, failure of the heart's action, freedom from anxiety on the part of the patient, and the tendency to death not averted, although the prominent symptoms had been relieved sixty hours before that event occurred.

"Is opium contra-indicated by the tendency to suppression of urine? That symptom was more marked in this case after the use of the morphia than before; and I have noticed in one child that the secretion of urine is remarkably diminished by the use of paregoric."

We have not been able to obtain sufficient information at present writing to enable us to lay before our readers a sketch of the epidemic of cholera now prevailing in the West. It appears, however, to have been introduced from Europe into New Orleans, and to have spread in the usual manner along the routes of travel in the Mississippi Valley, reaching as far as Cincinnati, where, however, it has not attained any severity. It has been denied that the disease is true epidemic cholera; but, in view of the large number of deaths that have occurred, we do not see what else it can be; and Dr. B. W. Avent, of Memphis, Tenn., writes us that it is cholera. The epidemic appears to be subsiding, and from present appearances its reaching this neighborhood is problematical; although a second fatal case of disease exactly simulating cholera occurred here on July 6, in the same quarter of the city as that of Dr. Githens.

THE material for our columns relating to the subject of cholera has accumulated to such an extent that a single number would not suffice to contain it. We have for this reason divided the lecture of Prof. Stillé, as well as the leading article upon disinfectants. The concluding portions of them will appear in the next number of the journal.

AS we go to press, we learn that the cholera, or at least choleraic disease, has appeared in Jersey City.

LEADING ARTICLES.

DISINFECTANTS.

WITHIN the last two or three years a great deal has been written upon the subject of disinfectants, with the result of unsettling what was considered at one time a settled matter; but, in the doubt which remains, certain principles can be seen looming up and apparently shaping themselves into positive truths.

Chief among these is the folly of attempting to disinfect the atmosphere. It may be possible to decompose sulphuretted hydrogen in the air by chlorinated lime; although even this is somewhat doubtful. It certainly is possible to cover up one stink by another: and this is what is probably done with the saucers of chlorinated lime yet seen about some hospital wards in which antediluvian ideas prevail;* but we have learned that contagion is certainly not sulphuretted hydrogen, any more than it is a bad smell, for the worst odor may exist without contagion, and the most deadly contagion may lurk in a fluid or an atmosphere free from odor.

Contagion appears to be one of two things,—organic alkaloids or other compounds of some sort, or else living germinal matter, animal or vegetable.

It is self-evident that a substance chemically powerful enough to disorganize organic compounds must be inimical to human life,—that a material sufficiently powerful to kill germinal matter of low organization must be destructive to germinal matter highly specialized and therefore highly sensitive.

It follows that any atmosphere capable of supporting human life is incapable of destroying contagion.

An efficient disinfection of a room, its atmosphere, and the furniture in it, certainly cannot be carried out with any person in the apartment. If it can be done at all, it will be by adopting the following plan:

Take a large iron pot† or caldron, put in it a little stand, such as the cheap tripod used by chemists, place on this an iron plate containing flowers of sulphur thoroughly wet with alcohol or (probably better still) with turpentine; underneath the plate set a tin alcohol lamp; then put the whole on bricks in the middle of the room, whose chimney, doors, and windows have been closely sealed, the drawers, closets, etc., having been widely opened. Light the lamp underneath the dish, and if the sulphur do not take fire previously, when it begins actively to melt, ignite it. Leave the room at once, closing the door. Unless the apartment become densely filled with the fumes, far beyond what could be supported by a human being, the attempt at disinfection cannot be of any service.

Even when this method of disinfection is carried out most thoroughly, it is still uncertain how completely the chamber is disinfected: to rely upon it to the exclusion of free, thorough ventilation afterwards, would be the sheerest folly.

It is evident that for ordinary purposes the only method of disinfecting an apartment is to be found in ventilation,—a dilution of the contaminated atmosphere by pure air until the point is reached at which the contagion is too slightly concentrated to affect human beings.

The question now arises, What is the province of disinfection? and the answer evidently is, To alter the constitution of liquids and solids.

We think here it is necessary to pause to get clear ideas about a matter which has been strangely confounded.

The cholera is approaching: the cry is to disinfect the cesspools. The cholera is here: the cry is to disinfect the discharges. It is evident that the objects to be gained in the two cases are different. There are no "contagion germs" in the cesspools, but putrefying organic matter. There is no putrefying organic matter in the cholera discharges, but a poison to be destroyed, —a poison whose nature is not known but is believed to be connected with life.

The point I want to make is that before the subject of disinfection can be made perfectly clear it is necessary to keep in view the two different results to be achieved, namely, the prevention of putrefactive fermentations in organic matter, and the destruction of germs already existent.

Having a distinct idea of what we desire to do, it is next in order to determine what we have to do it with.

Dr. Jeannel (*L'Union Médicale*, tom. xii.) arranges the disinfectants as follows:

1. *Oxidizing Agents*—air, oxygen, ozone, hyponitric acid.

2. *Dehydrogenizing Agents*—chlorine, hypochlorites, iodine, bromine.

3. *Deoxidizing Agents*—sulphurous acid, sulphites, hyposulphites.

4. *Desulphurating Agents and Coagulators of Albuminous Matters*—lime, salts of alumina, of zinc, of lead, of iron.

5. *Antiseptic Agents*, which kill germs—carbolic acid, its congeners and substances containing it, thymic acid, etc.

6. *Absorbing Agents*—charcoal.

It would not be difficult to make objections to this classification. Thus, the chief value of sulphurous acid as a disinfectant appears to depend upon its power of killing the low forms of life. It is, therefore, an antiseptic, and the possession by it of any powers beyond this is somewhat doubtful. Still, the classification is sufficiently accurate for practical purposes; so that we may take it for our guide in studying the subject of disinfecting putrefying matter. The method which nature employs for purification, as in water containing organic material, is by oxidation; and it seems as though in our present state of uncertainty the only

* By concealing the more apparent effects of bad ventilation, these so-called disinfecting saucers are really worse than useless: they actually do harm, and should be banished from the sick-chamber. The attempt to purify the air by means of them reminds one strongly of the wrath of Mrs. Partington when the Atlantic Ocean rose against her, and of her well-directed efforts to sweep it back with a broom.

† As this article is written for sensible people, it is not necessary to lay any stress upon the pot being large enough, and upon other precautions being used to avoid the risk of fire.

disinfectant worthy of absolute trust would be an agent capable of entirely oxidizing organic matter. Fire is such an agent; but it is too destructive, and often not readily applicable.

Permanganate of potash possesses the power of oxidizing dead organic matter freely; but, as every one knows who has applied it to a raw surface, its action on living tissue is feeble; and, according to Carmao-Dumenez and Demarquay, portions of lungs and liver immersed in a concentrated solution of the salt undergo putrefaction. I am not aware that experiments have been made as to its power of destroying living animal germs; and when to these facts are added its costliness and the large amount of it required for any service, because it uses its own oxygen only in the destruction of organic matter, it becomes evident that its practical value is slight. The same remarks apply in a still more forcible manner to the other substances in class No. 1.

In regard to the second class of substances, chlorine, in the form of chlorinated lime, is the only one worthy of attention; the extreme costliness of the other preparations renders them of no practical value. Chlorinated lime is certainly a very rapid and effective disinfectant, especially in regard to sulphuretted hydrogen. Its odor is, however, only a little better than that of the latter compound, and proof seems wanting that it acts with equal rapidity and effectiveness upon organic matter. Its comparative costliness and its bad odor certainly prevent its occupying the first rank as a disinfectant for uses such as we are now speaking of.

The third class of substances are far too costly for use as preventives of putrefaction on a large scale.

Lime, the first substance in the fourth class, is probably the oldest of all the disinfectants, and in some respects is efficient, although on the whole its general use is to be reprobated. It does not act merely as a desulphurating and coagulating agent: it, like the other strong alkalies, causes catalytically a slow oxidation of organic matter. Thus, ozone of itself will not oxidize olein, but if potash be added to the mixture the reaction commences at once; and it is notorious that a compost-heap which has lime in it rots—*i.e.* oxidizes—much more rapidly than one which has none of the alkaline earth in it. This action of lime is, however, too slow for ordinary purposes: moreover, there are very serious objections to its use as a disinfectant.

The poisonous principles contained in sewage, etc., whatever their nature may be, are probably volatile, and lime, acting as a strong base, sets free large quantities of ammonia in animal matter undergoing decomposition. It may be that volatile poisons, alkaloids, are liberated with the ammonia; but, whether they are or not, it is a well-known physical fact that a volatile substance in escaping carries off with it even non-volatile materials, and facilitates to a still greater degree the escape of principles only less volatile than itself.

Our choice of disinfectants for sewage, privies, etc., is therefore narrowed down to the fourth and fifth classes.

Owing to its much greater cheapness, the impure sulphate of iron—*copperas*—is by long odds the most available of the substances of the fourth class. The question of the comparative value of it and carbolic acid admits of not a moment's debate. The comparatively extreme dearness of the latter agent, its horrid odor, and its very marked poisonous properties, would forbid its use were it vastly more effective than the iron salt. In truth it is not. There is no reason for believing that carbolic acid affects any compounds formed before it is used; it certainly does not decompose sulphuretted hydrogen; it simply arrests decomposition by acting as a parasiticide, and when from any reason the percentage of it in a solution containing organic matter becomes reduced below a certain point it leaves the organic matter free to recommence putrefaction. Not so with copperas: it is antiseptic, but it also decomposes sulphuretted hydrogen, precipitating sulphide of iron; it is decomposed by ammonia, the oxide of iron, a persistent, powerful ozonizing agent being precipitated; it slowly but persistently attacks organic matter about it, oxidizing it and being reduced to a sulphide of iron. As copperas is very cheap, theoretically, it is the most efficient and valuable of the disinfectants, and practical use has shown, its price being considered, that it is the best. The common mistake is in not using it in sufficient quantity. At the ordinary drug-stores it is sold for from seven to fifteen cents a pound; and twenty-five pounds of it seems a great deal to the purchaser. Professor Genth, however, informs me that by the quantity impure copperas can be bought for seven-eighths of a cent a pound; and at this price in time of a cholera epidemic our streets should be watered with its solution.

The value of sulphate of iron does not rest, it must be remembered, upon theory only, but also upon experiment. In the *Zeitschrift des Oester.-Apothek.-Vereines*, February 10, 1873, Albert Eckstein published an account of his attempts to disinfect a privy which was used daily by one hundred persons, and the results are so interesting that they are here transcribed:

1. Two pounds of sulphate of iron in solution. After from two to three hours all bad smell had disappeared, but in twelve hours all the influence of the disinfectant was lost.

2. Sulphate of copper in solution, the same.

3. Two pounds of sulphate of iron in crystals; their effects lasted two days.

4. Sulphate of copper, the same.

5. Sulphurous acid in solution rapidly lost its effect, and was exceedingly irritating to the respiratory organs.

6. Two pounds of impure carbolic acid filled the house for two days with such a disagreeable smell that it was impossible to tell whether the original odor was destroyed or covered up.

7. Two pounds of sulphate of iron in a parchment sack exerted a disinfecting influence for three full days, and when the parchment sack was drawn up it contained only some dirty, odorless fluid.

8. Two pounds of the best chloride of calcium in the parchment sack disinfected the privy for at least nine days.

H. C. W., Jr.

(To be continued.)

SELECTIONS.

A CERTAIN SIGN FOR THE RECOGNITION OF CHOLERA IN THE EARLY STAGE.

DR. A. HERMANN has a paper upon this subject in the June number of the *Allgem. Wien. Med. Zeitung*, which is translated in *The Clinic* of June 28:

"All authors are agreed that the first urine after the collapse differs markedly from normal urine in *containing albumen, cylinders, hyaline and granular*, in abundance, and writers are tolerably unanimous in the opinion that the danger of the typhoid stage is due to the kidney disease which is thus developed.

"The discovery of the author consists in the *detection of albumen cylinders and epithelium in the urine during the time of the precursory diarrhœa*. If the examination of the urine show negative results, *cholera will not ensue*. The author has had now forty-eight cases in which to establish his discovery as a fact. In no one of these cases has he been deceived in his prognosis. It is very true that in *stadium asphycticum* little or no urine at all can be obtained for testing purposes; yet if catheterization be regularly practised (and it should never be omitted in cholera) enough may be obtained at some time for chemical and microscopical examination. The author does not claim priority in the discovery of albumen in the urine of cholera collapse. Simon and Hermann called attention to this fact in the third decade of the present century. The author's claim consists in the discovery of albumen in greater or less quantity during the stage of the '*diarrhœa premonitoria*.'

"Should an individual in health be suddenly attacked with diarrhœa, even during a cholera epidemic, *and should on examination no albumen be found in the urine, cholera will not develop*, not even if the individual be in such a position that he cannot protect himself in any way. Such a diarrhœa may even be maltreated and still it will not lead to cholera, but will resolve itself in time, even though it may have reached such a grade as to have been called cholerine or even cholera.

"But if albumen be found in the urine of an individual suffering with diarrhœa—with cylinders and kidney epithelium under the microscope—still the diagnosis of cholera is not absolute of course, as other affections may bring about this condition; yet as this manifestation is constant and never failing in cholera, as the collapse and typhoid condition are only observed in this condition, such a diarrhœa is to be diagnosticated as cholera when the other affections productive of albuminuria are excluded.

"It matters not whether the symptoms be light or severe, when albumen presents in the urine it establishes the existence of true cholera, and the graver symptoms will manifest in a short time.

"The author concludes his paper as follows: New observations have only confirmed me in the opinion before expressed that '*however severe and apparently choleraic the symptoms may be, the disease is not to be considered as true cholera if albumen be absent in the urine; on the other hand, the most anxious attention is to be directed to a case even in the earliest diarrhœa when the urine is albuminous.*"

MISCELLANY.

FRECKLES, it is said, are removed by the application, twice a day, of powdered nitre moistened with water.—*Southern Med. Record.*

ACTION OF THE BROMIDES IN PRURIGINOUS AFFECTIONS.—Dr. Guéneau (de Mussy) extols the efficacy of the bromides applied locally in pruriginous affections of the external and internal integuments. He recommends their use especially in pruritus vulvæ. He employs the bromides either in ointment or solution.—*Druggists' Circular.*

A NEW HYGROMETER, made in Paris by G. Smith, consists of strips of paper dipped in a cobalt salt solution containing common salt and gum Arabic. In dry weather it is blue, and in wet rose-red.

ORIGINAL LECTURES.

A LECTURE
ON EPIDEMIC OR MALIGNANT CHOLERA.

BY ALFRED STILLÉ, M.D.,

Professor of the Theory and Practice of Medicine in the University of Pennsylvania.

(Concluded from page 649.)

DIAGNOSIS.—The only diseases which malignant cholera resembles are the sporadic form of cholera, serous diarrhœa, and poisoning by certain irritant substances. I have already intimated the difficulty of making a distinction between sporadic and epidemic cholera, founded upon the symptoms alone. In both there may be vomiting and purging, coldness of the limbs, cramps in the legs, feebleness of the pulse, abdominal pain, and faintness. In the epidemic disease the additional symptoms seem to depend upon the profuse loss of fluids from the bowels. In the sporadic form the discharges are mucous and bilious for the most part, and take place first from the stomach and afterwards from the bowels; in the epidemic they are serous, or at least watery, stools, and for the most part exist for some time before vomiting sets in; when they become profuse the skin assumes a bluish color. The serous instead of bilious discharges, and the cyanotic color of the skin, are, then, the diagnostic marks of cholera asphyxia. But, as the cyanosis does not appear until the advanced stage, the only remaining symptom, and the only *symptom* at all, which distinguishes epidemic from sporadic cholera *during the first stage*, is the *watery evacuations* of the former disease.

Serous diarrhœa, or *diarrhœa aquosa* of some authors, resembles cholera in a certain degree: that is to say, watery discharges accompany both affections. These form the characteristic symptom of serous diarrhœa; and when they are accompanied with vomiting, as sometimes happens, there is nothing in the symptoms of the attack to distinguish it from a mild one of epidemic cholera. I do not know that this form of diarrhœa has ever become epidemic.

Malignant cholera also bears a strong resemblance to acute poisoning by arsenic. "The vertigo, derangements of the senses, the great depression, epigastric distress, thirst, cramps, the general coldness, and suppression of the urine,—all of these symptoms are common to both morbid conditions." But *burning heat and constriction of the œsophagus*, and *violent pain* in the *abdomen*, are occasioned by arsenical poisoning, and not by cholera; and this form of poisoning never produces such stools as distinguish cholera.

TREATMENT.—In estimating the value of the treatment of cholera, a very important consideration presents itself on the threshold of the inquiry. Is the treatment of the premonitary diarrhœa to be considered as forming a part of the treatment of cholera? No doubt an affirmative answer to this question should be given. I have already pointed out the fact that in a great majority of cases diarrhœa constitutes the first and forming stage of the graver affection, and constitutes also the first evidence of the action of the cholera poison. The prevalence of diarrhœa during cholera epidemics, whether or not the season or the other circumstances be such as usually occasion diarrhœa, shows that in each case the bowel complaint proceeds from the same cause. In the English epidemic of 1849, when the mortality from cholera was 53,241, that from "diarrhœa" was 18,869. The enormous number destroyed by the latter disease clearly indicates that the cholera poison produced diarrhœa where it did not occasion the more malignant disease. The treatment, then, of the stage of diarrhœa is in reality the treatment of cholera. I may add, what is of vastly more value than this pathological conclusion, it is *the only stage of the disease in which treatment makes a sensible impression upon the mortality*.

When the disease comes on gradually, in the form of diarrhœa, it can nearly always be arrested by the usual remedies for bowel complaint. These may consist of opium either with stimulants or with astringents. The stimulants most generally used are the essential oils of cajeput, cloves, cinnamon, peppermint, etc., with which chloroform, ether, or Hoffmann's anodyne may be associated. Probably such agents are particularly indicated when the attack has been somewhat sudden. The same may be said of hot drinks which are given at the same time, and which should contain some alcoholic distilled liquor in moderation. The patient meanwhile should be kept warm, and if necessary wrapped in blankets, and an effort made to force and maintain a free perspiration. If such remedies do not speedily diminish the diarrhœa, they should be discontinued. Owing to the depressing influence of the epidemic poison, these means will be of little value unless the patient be kept perfectly at rest. He should lie in bed, and not rise at all,—not even, if possible, to obey a call of nature. As a general rule, astringents are more efficacious than stimulants in checking the premonitory diarrhœa. Chalk mixture, with tincture of catechu and a little laudanum, is sufficient if the symptoms are very mild, and particularly if the stools continue to be brownish. But if they assume the serous character, it is better to resort to acetate of lead and opium. By many it is preferred to combine *calomel* with these substances, in the pilular form. The proportion of opium should *never be* large, and least of all on the approach of the fully-developed stage of cholera; for then it tends to depress and paralyze, instead of stimulating, the functions. At the appropriate period, pills containing one grain of acetate of lead and a quarter grain of opium may be administered every hour.

In the second stage of cholera, with serous vomiting and purging, the treatment becomes more difficult; for the action of medicines must be very

slight when they remain but a short time in the stomach and are copiously diluted by its secretions. In reviewing the long catalogue of those which have been prescribed during this stage, I can scarcely find one which is even claimed to have been effectual. Bleeding has nothing but the fanciful notions of enthusiastic gentlemen to recommend it. Alcoholic stimulants, ammonia, narcotics, astringents, quinia, emetics, even, and purgatives, have had their advocates; but no successful results attest their value. On the contrary, no well-informed practitioner would now place the least dependence upon them.

Alkaline solutions,—muriate of soda and sesquicarbonate of soda,—warm, and largely diluted, have been injected into the *bowel*, with the effect of replenishing the exhausted vessels and restoring, for a time, warmth to the skin, force to the pulse, and animation to the countenance; while they relieved the cramps and dispelled the cyanotic color of the skin. Similar solutions have been injected into the *veins*, with still more striking and encouraging effects. But these phenomena were like those produced by galvanizing a corpse: a sudden and almost miraculous development of energy displayed the semblance of reviving life; but hardly had hope been conceived before it was doomed to be disappointed. The symptoms returned; and usually no second resurrection followed the persistent employment of the remedy.

A plan for the success of which a persistent claim has been set up by many respectable practitioners is the one which was proposed by Dr. Ayre, of Hull. It consists in giving one or two grains of calomel every five or ten minutes, and one or two drops of laudanum with the first few doses of the drug, and in perseveringly continuing the same dose, at the same intervals of time, until the symptoms of collapse become materially subdued. From that time it is not claimed to do good, and may, certainly, be injurious.

Of other internal remedies, those of a stimulating class, and particularly brandy and wine, would seem to be suggested by the general prostration and exhaustion and the coldness of the skin. They have, accordingly, been used very extensively; and the general result of experience is that they are *worse than useless*. They not only do not tend to arrest the discharges and the progressive coldness, but, on the contrary, they augment the vomiting and distress.

Everything, besides what has been mentioned, that appears to be of any service, is beneficial only by moderating some of the more troublesome symptoms of the attack. Ice is generally grateful to patients in impending or actual collapse. It relieves the burning thirst, and, in many cases, seems to favor reaction, while it appeases the feeling of intense heat in the abdomen. Iced water may, in like manner, be given repeatedly, but not in such large quantities as, by their bulk, to excite vomiting. Cold carbonated water is very grateful to many patients. Lime-water, with milk, may also be tried, as a means of affording nourishment and controlling, in some degree, the vomiting.

A very eminent physician and medical writer of London insists that cholera patients should have none but hot drinks, because their bodies are already so cold. Fortunately, nature's voice is more authoritative; and cholera patients clamor for cold drinks and swallow them greedily, in spite of the theoretical conclusion that they ought to prefer hot ones.

A great variety of external applications have been resorted to for the purpose of retaining the blood in the cutaneous vessels, of maintaining the warmth, relieving the spasms, allaying the vomiting and purging, etc. Of these, the most commonly employed belong to the class of rubefacients. Sinapisms are applied to the epigastrium, or to the whole abdomen. Frictions of the extremities with liniments containing turpentine, ammonia, cantharides, or tincture of capsicum, or simply with dry and coarse cloths, and even ligature of the thighs, are commonly resorted to. But I doubt much whether any means which agitate, disturb, and exhaust the patient are likely to be useful. The revulsive action of mustard, however, is not liable to the same objection, and should certainly not be neglected; and ligatures around the thighs may also be tried. It is a curious and interesting fact that *heat* applied to the skin, so far from alleviating the symptoms and restoring the circulation to the surface, is almost always ineffectual, except in relieving the spasms in a few cases. This is strikingly true of *warm baths*, either of water or of vapor. Their depressing effects are sometimes marked and unmistakable, and are much complained of by the patients. At the outset of the disease they seem to be more efficient.

On the other hand, *cold water*, in the form of douche or affusion, is of decided efficacy in some cases, and much more grateful than warm applications. The patient is directed to be laid upon the floor, while cold water is dashed over him; or to be seated in a tub, while the water is poured rapidly over his body. Immediately he is to be dried, and wrapped in blankets, and after an hour or two the operation may be renewed. Frictions of the skin with *ice* have also been productive of advantage. Still, it must be confessed that the results of the treatment by cold water do not authorize its *general* adoption.

If, under the use of any of the means which have been enumerated, it is found that reaction commences, it becomes necessary to temper the activity of the stimulant remedies, but not to desist entirely from their use. To do so prematurely would be to expose the patient to relapsing into the cold stage. But they must be more moderately used. For if this were not done, we might have to regret producing a violent reaction hardly less dangerous than the original attack.

When this does occur under a decidedly sthenic form, it may be necessary to employ moderate depletion by cups or leeches to the back of the neck, in order to calm the cerebral excitement or relieve the stupor. For the same purpose, and where depletion is judged to be improper, cold lotions and ice may be applied to the head. Blisters to the epigastrium may be directed, to calm the vomiting, if it should continue, or to relieve pain in the

stomach. If the urine is not duly secreted, mild diluent and mucilaginous drinks are useful. Some persons recommend, also, the weaker salines; but the risk of renewing the diarrhœa should make us cautious in their use. Care should be taken to prevent distention of the bladder, either by applying warm fomentations to the hypogastric region, or by introducing the catheter. The management of the *convalescence* from cholera requires attention. The most important precepts relate to the *diet* and *exercise*. Premature and undue exertion is most sedulously to be avoided, as well as all exposure to cold, and all attention to business that involves anxiety and fatigue. The diet should be mild, digestible, and nutritious, and not too abundant. If, as is usually the case, the stomach digests feebly, it must be aided by the stimulant operation of cayenne pepper or a little mustard used with the food, and by bitter vegetable infusions, or a little quinia, taken before the principal meals. If diarrhœa recurs, the food must for the time be rendered less stimulant, and a few doses of chalk mixture or of bismuth, with catechu or with a little opium, may be prescribed. When, on the other hand, constipation follows the attack, it may be removed by allowing sound and ripe fruit in its fresh state, or, what is safer, stewed fruit; or else a small dose of castor oil or of rhubarb may be directed.

Such are the causes, characters, and treatment of cholera. I have endeavored to impress upon you, as the capital point in the discussion, the extreme importance of meeting the disease at the very threshold, whenever it does not assault violently and suddenly. There you are its master, and may safely and easily drive it away. But once it has passed that boundary and taken possession, you will have a sharp struggle with it for the victory, and too often will be compelled to leave it master of the field.

ORIGINAL COMMUNICATIONS.

ANAL AND PERINEAL NEURALGIA.

BY S. WEIR MITCHELL, M.D.

I HAVE met with a set of cases during the last few years which, so far as I know, are undescribed in the books, and which are sometimes very unmanageable. The disorder in question is a painful affection of the anal and perineal regions, accompanied or not, as the case may be, with spasmodic contractions of the anal muscles and of those of the perineum. This form of neuralgic trouble is met with now and then in locomotor ataxia, but so far I have encountered it only in men, and even in them it is rather rare, since in the numerous examples of this disease which I have seen at my clinic, or in private practice, it has occurred but in two cases.

One of these was a man æt. 38, who had been ataxic for nearly twelve years, during all of which time he had had frequent attacks of terrible neuralgia in the legs and arms. About once a month he is seized with agonizing pain in the anus and perineum. The pain has no relation to the state of the bowels, and invariably comes on soon after he goes to bed, and usually when he is nearly asleep. After a half-hour of singular torment, the anal muscles begin to quiver, or, as he says, "to work," and soon after the attack passes off. More rarely it continues longer or recurs during the night. An application of ice gives relief after a time.

In the other example there is no spasm, but the pain is always nocturnal, and is apt to awaken him from sleep.

In all the remaining cases which I have seen, the attacks followed masturbation or sexual intercourse, and in one instance was apt to take place after nocturnal emissions.

A lad æt. 18, who consulted me last year, told me that he began to suffer two years before, while practising self-abuse very freely. The pain began in the anus, and there was no spasm. It followed masturbation immediately, but not after every instance, and was most common when the indulgence in this vice had been excessive. A few months before I saw him he had ceased to masturbate, but the pain still came on about once a week, and usually soon after he went to bed. Firm pressure on the anal region gave some relief; but he was not finally cured until after a long course of tonics and of sea-bathing. I have met with other cases of the same sequence, and in old men I have also seen a few examples in which there had been no sexual excitation to account for the pain.

It is much more rare after sexual intercourse; but in two of the most severe examples this relation existed. One of them was a young man, married some three months, who told me that after having sexually exhausted himself he had his first attack, which was very violent. The pain began in the anus and extended to the perineum, and there was but very slight spasm. After this it followed, occasionally, sexual intercourse, but was never again so severe. I enjoined greater temperance in the marital rites, and he suffered less and less until after an ague which the following spring affected his general health. Then there were frequent and severe paroxysms, sometimes without any previous indulgence. As his health improved, the local trouble got better, and has now ceased to annoy him.

I have seen but one case as severe, and this in an unmarried and continent bachelor æt. 35. The pain returned almost every night for two weeks, and was finally cured by suppositories of belladonna and opium. The spasms were lasting and very painful, and came on with the earliest of the deep-seated dull pains in the rectum. I have not met with any, save the ataxic cases, which resisted treatment for a length of time.

I have described in the *American Journal of the Medical Sciences* for July, 1873, a curious series of ataxic cases with neuralgia, in which permanent ease was obtained by absolute rest. In one of these there was slight but frequent anal neuralgia, which ceased with the relief of the pains in the limbs.

NOTES OF HOSPITAL PRACTICE.

CHILDREN'S HOSPITAL.

Reported by HENRY M. ESTRAZULAS, M.D.,
Resident Physician to the Children's Hospital of Philadelphia.

EXCISION OF THE KNEE IN ARTHRITIS.

ROBERT M., æt. 9, American, was admitted on the 24th of May, 1872.

The patient had been under surgical treatment at the "Union School," and presented himself to us with a swollen and hard knee, stiff, flexed to nearly a right angle, and covered with superficial ulcerations. The general health was good. The patient traces the origin of the disease to a fall upon an oyster-shell about a year ago. Pain, swelling, and stiffness followed, rendering the limb useless, and obliging the patient to go about on crutches.

When admitted to the hospital, the patient was put to bed, a straight splint applied, and the ulcers dressed.

When these were healed, the external ham-string was subcutaneously divided, the limb forcibly straightened and kept in position by a splint.

After this the tendency to retraction continued, and consequently the operation for excision was decided upon, though postponed till the summer should be over.

On the 5th of October the operation was performed by Dr. H. Lenox Hodge, as follows:

A straight incision was made beneath the patella, and was carried slightly curved towards the femur. The skin was dissected back, and the joint opened. The ligaments were found ulcerated, and pus burrowed underneath the patella and in front of the thigh.

The patella was removed, and then, flexing the limb, sections of the condyles were taken off obliquely below the epiphysis. The head of the tibia was next sawn from below upwards, the leg extended, and both ends of the bone brought together. The wound was dressed with sweet oil, the incision was closed with lead sutures, and the limb put on Packard's splint.

Little febrile movement followed; and a few days after, extension by weight was used. This was substituted by a posterior straight splint. The wound healed up well, and with no complications. Six weeks afterwards a pasteboard splint was applied, and the patient was allowed to go about on crutches. On March 14 the patient was discharged, in excellent health, and with the following results:

Patient walks very well, and without any assistance. Leg firm and united, and slightly flexed. Femur slightly prominent inwardly. Foot slightly everted while walking; it is normal while standing. Shortening, one inch and a half.

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,
Of Philadelphia.
Reported by J. EWING MEARS, M.D., of Philadelphia.

(Continued from page 629.)

CASE 239.—A solid malignant tumor of the right ovary, accompanied by ascites; incision about seven inches in length; death on the thirteenth day.—June 17, 1871, Mrs. J. A. O., of Wilmington, Delaware, consulted Dr. Atlee in reference to an abdominal tumor. She was 32 years old. Menstruation commenced at twelve years of age, continued regularly for three months, was then suspended for a long time, and, when it returned, occurred every three weeks until she was married. She was married in March, 1863, after which she became more regular. She had three children; the youngest was two years old. Lactation was free, and she did not menstruate while nursing. Latterly the menses had been scant and continued two weeks.

The patient first noticed the tumor on the 19th of April, 1871. Three weeks before Dr. Atlee saw her, Dr. Wales, of Wilmington, Delaware, examined her. On the 15th of June she was tapped by Drs. Wales and Bush, removing eighteen pints of amber-colored fluid, containing, after standing, a whitish sediment. The fluid coagulated by heat.

Although tapped only two days before Dr. Atlee saw her, she was as large as a woman at full period of utero-gestation. There was evidently an accumulation of fluid, to the amount of six or eight quarts, in the cavity of the peritoneum. The resonant sound existed over the highest point of the abdomen in all positions of the body. A tumor could readily be detected immersed within the fluid. It was very movable, slightly uneven, and felt like a compact multilocular ovarian tumor. The uterus was central, movable, and non-adherent to the tumor, as both could be rubbed on each other and moved independently of one another. The pelvis was free from hard deposits, and did not indicate the presence of malignant disease. The lower portion of the tumor could be felt in the superior strait of the pelvis, anterior to the fundus uteri, and communicated to the hand a sensation resembling that of a uterine cauliflower excrescence. The tumor was freely movable, could be pushed high in the abdomen, and to the opposite side. An examination by the speculum revealed granular inflammation of the os uteri.

The patient considered herself pregnant; but Dr. Atlee was satisfied that she was not.

The diagnosis was a compact multilocular tumor of the right ovary, with peritoneal effusion.

June 26, 1871, Dr. Atlee removed the tumor, assisted by Drs. Wales, Bush, Kane, Johnson, and Grimshaw.

The tumor was attached to the right side of the uterus, and kidney-shaped. The pedicle was broad and dense, and was attached to the concave surface of the tumor. It was secured in ¾-inch space of Atlee's clamp.

The case terminated fatally on the thirteenth day. No autopsy. Dr. Wales wrote, "I am rather inclined to the opinion that the operation for the removal of the tumor was successful; but the diseased action of the body causing the dropsy still continued, and caused her death."

Dr. Mears made an examination of the tumor, and described it as "a specimen of scirrhus or fibro-carcinoma of the ovary."

Case 240.—Unilocular ovarian cyst; tapped three times; parietal and omental adhesion; incision about three inches long; recovery.

August 9, 1871, Dr. Atlee visited Mrs. E. H., at Pittsburg, for the purpose of performing ovariotomy. She was 40 years old, and first menstruated when very young; was always regular,—discharge lasting one week. She was married at the age of thirty-one; had four children, the first parturition being difficult and followed by metritis and puerperal peritonitis. She nursed her children one year; had good lactation, and her menses returned one month after child-bed and continued regularly while nursing. Her youngest child was about sixteen months old. With the exception of her present disease, she has always enjoyed good health. She has recently become emaciated.

She first noticed the tumor in February, 1868, at the birth of her third child. Her labor was superintended by Dr. Landis, of Hollidaysburg, and after the birth of the child the abdomen remained so large that it was at first supposed that another child would follow. The

size of the abdomen afterwards did not seem to increase, and she in due time became pregnant again. During gestation the motions of the child were felt in the lower central part of the abdomen. She was confined with this, the fourth, child in April, 1870. Five weeks after its birth she was tapped by Dr. James King, of Pittsburg, who removed twenty-six pints of clear fluid, containing masses of lymph. She was tapped twice afterwards, the last time about two months before Dr. Atlee saw her, when the fluid was more milky in color and contained a larger quantity of masses of lymph. She was menstruating at the time of Dr. Atlee's visit.

The abdomen was larger than that of a woman at full period. It was uniform in shape, with rather greater prominence over the right side. It was smooth and elastic over the whole surface, excepting over a point in the left side. Fluctuation was distinct. The xiphoid cartilage was elevated to an angle of forty-five degrees. The uterus was central and movable. The pelvis was free. The sound entered only one inch.

Diagnosis.—Unilocular ovarian cyst of the right side, with some deposit in its left wall.

The following gentlemen assisted at the operation for the removal of the cyst: Drs. James King, Bruce, Mowrey, Gallaher, Pollock, Coffey, C. B. King, Sutton, Le Moyne, and Messrs. Rea and Estep.

About six or eight ounces of blood were lost during the operation. The uterus was enlarged; the left ovary was healthy, having a corpus luteum quite apparent. The tumor consisted of the right ovary, was unilocular, and had in its left wall some secondary deposits.

The patient recovered.

Case 241.—Multilocular ovarian tumor; most extensive visceral and parietal adhesions; incision five inches in length; death in thirty-two hours; autopsy.

August 3, 1871, Mrs. W. H. B., of Port Gibson, Mississippi, came to Philadelphia to consult Dr. Atlee in reference to an abdominal tumor. She was 36 years old, and had first menstruated at twelve or thirteen years of age. She was tolerably regular. Occasionally she had attacks of chills and fever, at which time the menses were irregular. She always had dysmenorrhœa. She was married at the age of nineteen, had one child at the age of twenty-one, which lived nine months.

She first noticed a tumor, as large as the fist, in the right side, in the fall of 1866. It was hard, and slightly movable, and continued regularly to increase in size. At that time her weight was two hundred and four pounds, being a very large and fleshy woman. In 1867 her physician, Dr. Thomas, sent her to New Orleans to consult Dr. Stone. On her return Dr. Russel took charge of the case, and finally directed her to consult Dr. Atlee.

The following is a report of the patient's condition: She is tall, and very much emaciated and feeble, with a pulse over 100. The abdomen is very large and prominent, and most developed below the umbilicus, so as to be somewhat pendulent. There is resonance in the epigastric and right hypochondriac regions, and dulness elsewhere. The tumor is decidedly multilocular; the cysts generally small, with some very hard deposits, particularly in a line with the left linea semilunaris. The accumulation of ascitic fluid exists in the hypogastric region. The superior strait of the pelvis is impacted by the mass. The uterus, which had formerly been in a state of procidentia, is elevated above the symphysis pubis. The os can just be reached, and is singularly malformed, representing two long nipples, with the entrance between them. The sound enters two and a half inches, going towards the left groin into a small mass. This mass, before menstruation, enlarges to the size of an egg, and again diminishes as the discharge occurs.

She measures round the waist thirty-four inches; round the umbilicus forty-six inches; from sternum to umbilicus thirteen inches, to pubes twenty-seven, and between the two ilia twenty-five inches.

Diagnosis.—Multilocular tumor of the right ovary. Prognosis, unfavorable.

August 12, 1871.—The following gentlemen assisted in the operation: Drs. Drysdale, Mears, Keen, Hoffman, W. Lemuel Atlee, Rex, and Barr.

During the operation the patient became very weak, and required stimulation.

Death in thirty-two hours, from shock and hemorrhage, as ascertained by autopsy.

This case belongs clearly to the second class of desperate cases.

TRANSLATIONS.

THE PHYSIOLOGICAL ACTION OF PROPYLAMINE.

Read by M. Laborde before La Société de Biologie. Translated from the *Gazette Médicale*, June 7, 1873,

BY JEAN PAUL BONSIEUR, M.D.

I HAVE the honor to submit to the Society the results of a series of experiments which I have pursued for some time to determine the physiological action of propylamine.

This drug, in spite of its disagreeable odor, is now very much in fashion. Its therapeutic employment is not new, it having been used in Russia almost as a panacea. It has recently been brought into notice in this country by Dujardin-Beaumetz. Already numerous clinical experiments have been made on man until other evidence seems unnecessary; but therapeutic tests are always more or less empirical, and should invariably be preceded by a knowledge of the physiological and toxic action of the drug. *Primo non nocere.*

The only acquisitions, up to the present, relative to this subject, were as follows: Some observations of M. Guibert on himself, who considered this substance to be a slight excitant of the skin and mucous membranes, and an hyposthenic of the arterial system. With Professor Coze and Dr. Fargier-Lagrange, it diminished the quantity of urine, lowered the activity of the circulation and temperature, and exerted a sedative action on the nervous system.

According to Dr. G. Namias, it augmented diuresis, diminished the number of pulsations, lowered the temperature and arterial tension. The experiments of M. Rabuteau, made with chlorhydrate of propylamine, seemed to demonstrate that this agent immediately arrested the action of the heart, as occurs under the influence of one of the so-called cardiac or muscular poisons. (See thesis of Bourdet, Paris, April 25, 1873.) The substance called propylamine is not a fixed composition, always of the same identity. Without entering into its chemical composition, I will state that I have used for my experiments both the impure drug and also trimethylamine. The experiments were made on mammals (dogs and rabbits) and frogs; the latter animals answer extremely well to show the action of this agent. With the mammals the drug was exhibited by the stomach, and by subcutaneous injection; with the reptiles, however, the inter-digital membrane was made the absorbing medium, by fixing the animal vertically in a flask and allowing the feet to be immersed in the fluid below; by these means the process of absorption is maintained free from interruption.

When a gramme and a half or two grammes were injected beneath the skin in the groin of a young and vigorous rabbit, in the course of three-quarters of an hour, or an hour, the animal became restless, its fur

rough, a general trembling ensued, it started at the least touch, the respiration was notably accelerated, the cardiac action became more frequent; later it became distressed, gathering itself up in a corner, and walked with great difficulty when excited, the irritation causing lively reflex action, with shaking and trembling. The respiration became more and more frequent, the cardiac action more precipitated, but its impulsion appeared weakened; finally the animal fell into collapse, with signs of asphyxia, and died. On autopsy there was found a discoloration of some extent of the abdominal integument about the point of injection, with a gangrenous condition, accompanied by emphysema. The examination of the viscera showed patches of pulmonary congestion, points of vesicular emphysema, and some spots of subpleural ecchymosis. The heart contained large black clots in both cavities. The kidneys showed a state of congestion; the bladder was filled with urine, non-albuminous, with an ammoniacal odor.

Under these experimental conditions two phases were displayed: the one a period of trembling, characterized by convulsive succussion, agitation, increasing to excito-motor action, with hyperæsthesia, and an augmentation of the cardiac and respiratory movements; the other, a period of depression, of collapse, characterized by a certain degree of motor paresis, and terminating in asphyxia. The experiments with frogs confirmed the first results; but they further determined the state of the muscular and nervous systems. We proceeded, as already indicated, to place the inter-digital membrane of a vivacious frog in a bath of trimethylamine; after absorption had proceeded for half or three-quarters of an hour a lively agitation occurred, soon followed by slight convulsive starts, fibrillous twitching of the muscles of the feet, jumping at the least noise or disturbance of the flask, dilatation of the pupils, increase in the movements of respiratory deglutition, and also of the cardiac pulsations. As the influence of the drug asserted itself, the agitation ceased, the reflex excitability grew less, the muscular action disappeared. At the same time a progressive decrease of the cardiac movements occurred: from 64 to 68 beats to the minute at the commencement of the experiment, they fell to 34, 20, 12, and, finally, were suspended; the animal succumbing in one hour, one hour and a half, sometimes two hours, after the exhibition of the drug. In the course of the experiments the sciatic nerve was laid bare, in order to examine the state of the motor excitability, which is so notably increased, as is also the muscular contractility, during the stage of excitement. Both persist to the last, but progressively diminish in power. The inter-digital membrane presented a very anæmic appearance.

The experiments on the reptiles truly demonstrate, as in the mammals, the two phases in the action of this drug,—the phase of excitement, characterized by exaltation of the physiological properties of the nervous and muscular systems, and the phase of collapse, truly toxic, marked by the depression and cessation of the functions which belong to the same systems.

It only remained to determine which of these systems was first affected by the drug. The whole of the previous experiments tended to demonstrate that the nervous system was first brought under its influence, as shown by the hyperæsthesia, convulsive trembling, and the augmentation of the excito-motor phenomena; the results of the following experiments definitively settle the question.

On section of the dorso-lumbar nerves in a frog under the action of trimethylamine, destroying communication between the cord and posterior extremities, the convulsions do not occur in the latter, yet the muscular contractility remains intact. If the vessels of these parts be ligated, the abnormal excito-motor phenomena take place coincident with those of the other limbs.

The following experiments show clearly that the drug acted directly neither on cardiac nor muscular contractility. Four grammes of tremethylamine dissolved in twenty grammes of water were injected into the cardiac extremity of the crural vein of a young dog, vigorous and of ordinary size. Immediately general tetanic rigors occurred, with diaphragmatic spasm, momentary arrest of the respiration, and accelerated cardiac action; after a long inspiration the animal recovered, and respiration became regular; but soon an active excitement ensued, with violent struggles, and the ejection of abundant bile from the mouth; the limbs were shaken by convulsive action, which gradually moderated. After being released it soon became immovable, lying flat on the side. The following day it showed complete recovery. We then subjected it to the following experiment: Section of both pneumogastric nerves with artificial respiration; after some repose five grammes of trimethylamine diluted in twenty-five grammes of water were injected into the cardiac end of the crural vein; during the injection, which was made very slowly, the heart showed an appreciable modification both in frequency and in rhythm. The injection renewed with four grammes of the drug caused only a slight increase in the pulsations. On autopsy the surface of the endocardium showed considerable irritation, with numerous ecchymoses.

To complete these researches, we administered the drug, to dogs, every day for a considerable time, by the œsophageal tube, in doses progressively increased. A dose of two grammes to two and a half given to a dog of medium size will produce almost instantaneous vomiting. In less doses, anxiety, immobility, a condition of distress, general muscular trembling, accelerated action of the heart, distaste of food, marked emaciation; sanguinolent urine is voided at the end of six days, charged with biliary and coloring matters in abundance; a great susceptibility, hyperæsthesia, increase of reflex excitability. Such are the chief phenomena under these conditions.

Chronic Poisoning with Chloral Hydrate.—In the June number of *The Practitioner* there is a paper translated by the editor of that journal from the writings of Dr. Ludwig Kern, detailing a series of morbid phenomena which appeared in the course of a continuous employment of chloral. The most prominent symptoms were extensive cutaneous erythemas, and pustular or papular exanthemata. The vessels of the head and face were first dilated; but in pronounced cases this condition extended downwards, following by preference the course of the larger nerve-trunks. Conjunctivitis, inflammations of the mucous membranes, and congestions in various parts of the body were also noticed. A very important symptom was an interference with respiration, sometimes slight and sometimes amounting to actual dyspnœa, endangering life. The effects of chloral upon the skin and mucous membranes, and the dypsnœa produced by it, may all be explained by the assumption that it operates upon the vaso-motor centre and the medulla oblongata, and that its paralyzing influence extends thence to the peripheral branches of the affected nerves.

There was another class of cases in which both the quality of the symptoms and their greater or less extension in the organism indicated a distinct change in the composition of the blood. They were attended with petechiæ, subcutaneous ecchymoses, colliquative diarrhœa, bronchitis, diffuse abscesses, high and continued fever, and all the symptoms of profound blood-poisoning.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 19, 1873.

EDITORIAL.

CHOLERA.

OUR readers, no doubt, will remember that we failed in our last issue to lay before them any information of much interest concerning the epidemic of cholera prevailing in the West. Owing to the kindness of our correspondent, Dr. Ramsey, of Knoxville, Tennessee, and to the arrival of some of our Western exchanges, we can to-day, in a measure, fill the gap in our last issue.

About two months ago, cases of what bore a strong resemblance to malignant cholera, in symptoms and termination, were reported in New Orleans, —it is said, shortly after the arrival of a vessel from Odessa, where the disease is prevailing. A steamer leaving New Orleans for Cincinnati lost a number of deck-hands or passengers on its way; and not long afterwards cases of the disease made their apperance at Memphis, and at points on the river below.

Following the lines of travel, the disease continued to spread, passing up the river to Paducah and Cincinnati, and along the railroads to Nashville, Gallatin, Murfreesboro', and finally into Eastern Tennessee. Nashville has, as in all previous epidemics, suffered very severely. On June 20 seventy-three deaths were reported there from cholera, and the daily mortality ranged from forty to seventy during the week from the 15th to the 22d. Probably, however, the little town of Greeneville, on the main line of railroad, in the extreme eastern part of Tennessee, has been the most severely punished of any place as yet,—punished for the most reckless disregard of the first principles of sanitary science, if not of those of common decency.

By death and fright the population is said to have been reduced in two weeks from twelve hundred to three hundred. By the 1st of July all business whatever had stopped, except a very limited traffic in food and attention upon the sick and the burying of the dead.

As almost all of the well-to-do had fled, and as no work was to be had, great destitution prevailed; and even famine might have been added to the miseries of the poor, had not the surrounding towns answered their cries for help. The cause of this great malignancy is not hard to discover, and is clearly shown in the following extract from Dr. F. A. Ramsey's official report to the mayor of Knoxville:

"More than a quarter of a century ago, an immense pit was dug in the very centre of the town, and a cloaca erected over it with capacity sufficient for the accommodation of the entire community during all these years. A very short time before the erupting of the disease by which the town has been depopulated, an *energetic* citizen ingenuously emptied this pit, and had the contents wagoned through the town and spread upon the face of a hill on the northwest verge of the corporation, the contents from the pit spreading over a very considerable surface of wet ground, exposed for several days to a fiery sun. Then there occurred the heaviest rain that any citizen of Greeneville had ever witnessed. It was the eastern side or slope of the hill on which the deposit was made; and, of course, the wash of the hill was into and through the town. The heavy wash of this rain carried all the surface soil from the hill, and, as the water covered an area equal to three-fourths of the corporate extent of the town, the *débris* from the pit which it held, fairly divided, if not dissolved, was distributed to just so much of the surface of the ground. But this is not all: the *pile* is yet incomplete! The town of Greeneville is a town of gardens, each garden-owner indulging an emulation as to who would have the best grapes,—all the gardens having grape-arbors of less or very large extent. All the inhabitants of the town believed that the fæcal deposit made by men, women, and children is of all things the best to give vigor to the grape-vine, fulness to the grape, and luscious delicateness to the flavor and mellowness to the odor of the juice of the fruit. Every cloaca in the town surrendered its contents, and at the root of each main stem was buried, in wet earth, a pile of human excrement. . . . In the overflow several wells were contaminated, the waters of which, of course, are poisonous now, but outside of the overflow there is no reason to believe the water of the town to be otherwise than pure. The cloacæ of the town are without pits, and are all built upon a natural or artificial drain or sewer, communicating with a creek that passes from a northwest point, running east and then south through and on the edge of the town, and soon entering and pass-

ing through farms more or less contiguous to the town. The stock on these farms drink the water of this stream from Greeneville; and as far distant as five miles from town, on this stream, cases of the disease have occurred. In no instance of occurrence of the disease in Greene county has it been difficult to demonstrate a direct or indirect contact with Greeneville atmosphere and Greeneville water, contaminated by human fæcal matter."

Wherever the disease has prevailed, the colored population have suffered more than the white, largely, no doubt, because they through poverty frequent the more unhealthy neighborhoods and live in the greater squalor and filth.

Thus, in Nashville on one day forty-nine out of seventy-three deaths were of colored persons. Even when the mortality exceeded seventy a day, the city proper was comparatively healthy; the epidemic prevailing in the low bottoms along the river.

A very singular attempt has been made by some of the most talented physicians of the infected localities to disprove that the disease was Asiatic cholera, and it has been over and over affirmed that it was simply "sporadic cholera." As to the term "Asiatic," we do not stickle for that; call it Mississippi cholera if you please; but we do insist that a disease which spreads over hundreds of miles of country, which depopulates villages and strikes terror into cities, is *epidemic:* if it is simply sporadic, we want to know under what circumstances a disease is epidemic.

Again, we still hold to the belief that two diseases which are identical in mode of spreading, in symptoms, in results, or, in other words, diseases whose natural history is the same, are one and the same thing. The present epidemic has passed along routes of travel, has been propagated by water contaminated with fæcal matter, has attacked most freely those living in low and crowded portions of cities, has produced in its victims all the symptoms and results of true cholera, and is, therefore, in our opinion, nothing else than cholera.

REPORT OF THE MUNICIPAL HOSPITAL.

JUSTLY to give praise is as to give alms: it blesseth him that giveth, as him that receiveth.

It is a luxury—and, we may say, in these later times a rare luxury—to be able to praise anything connected with our city government; but it appears that our Board of Health have availed themselves of the opportunity which they to some extent created for adding to our knowledge of the smallpox,—2377 cases of smallpox, genuine and modified, 743 preventable deaths. Well, it strikes us that this is a pretty dear price to pay for even the excellent report of Dr. William M. Welch, which lies on the table before us. Smallpox is at best a disease of low degree, though of most ancient pedigree,—a pedigree so ancient, so investigated, a face so familiar, a habit so well known, that even Dr. Welch is not able to bring forward anything actually new out of his experience. We notice, however, several things of interest. One is a most gratifying exhibit of the advance of the art of diagnosis among us. Out of over two thousand cases sent to the hospital as smallpox, there were only four cases of debauch, one case of cerebro-spinal meningitis, one of pneumonia, one of pleurisy, one of rheumatism, one of scarlet fever, and one of typhoid fever; and, as we are told that these cases were all or almost all well advanced in their respective diseases, the result is still more gratifying to our professional pride.

As showing the value of vaccination, we note that not a single person connected with the hospital, who had been revaccinated, contracted the disease; while, on the other hand, some three or four of the nurses, who had been affected by smallpox previously, and were not vaccinated, took the disease a second time.

The following extract in regard to vaccination seems worth copying:

"A fanciful opinion was once held by eminent authors that if a pregnant female undergoes smallpox without aborting, the infant, which was supposed to have passed through the disease at the same time, would remain through life unsusceptible to either smallpox or vaccination. We have found, however, that children born under these circumstances respond as readily to vaccination as any other children; so, likewise, have we seen them contract smallpox."

A curious case showing the insensibility to pain sometimes caused by delirium occurred in the hospital during the epidemic. A female, cunningly embracing an opportune moment, ran quickly, and sat down on the open fire-grate. There she remained, apparently insensible to pain, for while her clothing was burning around her, and her flesh charring, she was violently resisting the efforts of the nurse to extricate her.

In conclusion, we express our opinion that the pamphlet of Dr. Welch is worthy of preservation as an excellent and truthful report of a most disgraceful epidemic. We hold that as in war success is the great criterion of the ability, or at least of the value to the state, of a general, so is success in the preservation of a city from epidemics the touchstone to decide the efficiency or inefficiency of a Board of Health; and we think that ours has been tried and found wanting.

WE give place with great pleasure in our columns to a letter concerning the editorial which appeared in our issue for June 27 upon the vacancy in the chair of anatomy at the Jefferson Medical College.

It is possible that if our *composite* friend will carefully re-read our article he will find that our opinions are not so far apart as he imagines. To elect an inferior man to a professorship in a medical college because he is the son of a professor is a gross outrage; but it is certainly no less a gross outrage to reject a superior man because he is the son of a professor. In Philadelphia, of recent years, it has seemed to be a valid objection against a man that he is a relative to a professor, and, while it would be easy to point to instances of this, not once, to our knowledge, has kinship to a teacher in the school aided in the election of a professor.

As matters stand, certainly there is no ground for accusing our electing boards of nepotism.

What the views of the mass of the profession may be we have no better means of determining than has our correspondent; but we certainly still believe the opinions expressed in our editorial are just and true.

The case of Dr. Alexander Simpson illustrates very forcibly one of the points which we endeavored to make in our former editorial. From all accounts, in that instance it became the duty of the medical press to speak out plainly in regard to the matter. In the canvass which has just suffered a miscarriage, certainly there was no such inequality among the candidates. If the matter had been left to a vote of the alumni, or even of the professors, so far as our information goes, no man could have predicted what the result would be.

If under such circumstances the medical press attempt to direct the various currents, if in every canvass each individual journal is to have its own candidate, the whole matter takes on a partisan appearance, and when the right time comes for a word to be spoken with authority, even the united voice of the medical press is but as some one babbling by the wayside.

LEADING ARTICLES.

DISINFECTANTS.

(Concluded from p. 655.)

IF the chloride of calcium spoken of by Eckstein be as efficient as he claims it to be, it ought to be one of the most commonly used disinfectants. So far as I have been able to learn, only the pure form of it is in the market, and this commands a comparatively high price for other than sanitary uses.

Enormous quantities of it sufficiently pure for disinfecting purposes are said to be thown away, as a waste product, in all alkali-works; and its utilization would be a great benefit. E. C. C. Stanford, Esq., of England, in 1872, proposed its use, establishing its value by an elaborate series of experiments proving that of all the chlorides it is the most powerful for its price, and is decidedly superior to "*chloralum*." He recommends it in the form of solution containing twenty-five per cent. of the solid salt, and acidified with twelve per cent. of hydrochloric acid. This increases its power, and is a harmless addition. As it does not make a black precipitate with sulphuretted hydrogen, the chloride of calcium is better than copperas for ordinary household use. The solution of Mr. Stanford appears to be a most excellent form of it for many purposes, but for others the solid form is best. Thus, there is always great difficulty in keeping urinals in houses free from offensive odor: this is said to be entirely obviated by putting a lump of chloride of calcium in the urinal; it lasts a long time, as it dissolves very gradually, and keeps the urinal perfectly free from odor.

Whatever disinfectant, however, be used, it must never be allowed to take the place of *cleanliness*. Large accumulations of organic matter practically never are, if they indeed can be, thoroughly disinfected.

As has already been stated, it is practically impossible to disinfect the atmosphere; and therefore it becomes the more important to destroy at once disease-germs wherever they exist in a solid or a liquid. The practical deduction from this is, that in a disease like cholera, in which the poisonous matter is chiefly—or at least is believed to be—emitted with the stools, the latter should be attacked the instant they leave the body. No patient suffering from cholera should be allowed under any pretence to use a water-closet or privy, but always a closed receptacle in which some material capable of destroying the disease-germs has been previously placed. In this way the *materies morbi* is reached as soon as possible after leaving the body, and has not nearly so great chance of doing harm as when the stool is only disinfected after the patient has arisen from it.

The question next comes up for consideration as to what substance shall be employed for destroying the germs already existent in the discharges. Here especially has the prior place been claimed for carbolic acid. Granting, it is said, that it is not a disinfectant, it is a prince among antiseptics. The most convenient known test of the activity of an antiseptic—*i.e.* a destroyer of disease-germs—is believed to be its power of killing bacteria and similar low forms of vegetable life. Now, the experiments of the great advocate for the use of carbolic acid (Dr. Sansom) have shown that a large number of substances are more active in destroying microscopic organisms than is carbolic acid, and that the corrosive sublimate is about eight times as strong, one part of the mercurial salt in 6000 parts of water sufficing to kill organic germs, whilst one part of carbolic acid in 750 parts of water is required for the same purpose.

When it is further borne in mind that the odor of carbolic acid is most penetrating, permanent, and offensive, that it does not readily dissolve in the various liquids desired to be disinfected, and that it is so terribly poisonous as to have no advantage on such score over the corrosive sublimate, I think it may be well affirmed that when small quantities of the disinfectant are needed, as in cholera cases occurring in private practice, the bichloride is more available than carbolic acid. Moreover, corrosive sublimate actually alters organic compounds, parting with a portion of its chlorine, and being reduced to calomel.

I think, therefore, that for destroying the germs of disease, as in the stools of cholera, corrosive sublimate is preferable to carbolic acid, and is, indeed, on the whole, the best known substance for practical use.

Corrosive sublimate dissolved in Labarraque's solution would, I believe, make the best disinfectant for the purposes now being spoken of,—certainly far more efficacious than carbolic acid, much more manageable, no more poisonous, and cheaper.

It is, however, a question whether copperas, in saturated solution or in powder, freely used, is not, after all, the best material for rendering choleraic discharges harmless. The salt is so cheap that the excreta might be saturated with it at a scarcely appreciable cost, and, so used, it would certainly kill any living germs.

In conclusion, let us sum up the points which it has been attempted to make in this article:

1. It is useless to attempt to disinfect the atmosphere; and therefore great care should be exercised to destroy, as far as possible, the poison-germs so soon as they leave the body.

2. Copperas is the most available disinfectant for ordinary purposes; in certain cases (chiefly for urinals) chloride of calcium is very good.

3. Carbolic acid is not disinfectant, but antiseptic, and, on account of its odor, is very disagreeable; further, it is not so efficient as some other substances for the purpose of killing disease-germs, and for the purifying of cholera discharges either a mixture of corrosive sublimate and Labarraque's solution, or copperas in solution or powder, is to be preferred.

There are in the market various patent or proprietary disinfectants, concerning which I have said nothing, for several reasons. In the first place, I am not able to perceive exactly why a physician should use a patent disinfectant, when he utterly scouts any other proprietary medicine. In the second place, I have not yet seen any proof that these substances are superior to our ordinary disinfectants, but much evidence to the contrary.

H. C. W., Jr.

Curative Action of Ipecacuanha in Diarrhœa.—Dr. Thorowgood, before the Clinical Society of London (*Lancet*, May 24), read notes of two cases of persistent and alarming diarrhœa which yielded promptly to doses of from two to five grains of powdered ipecacuanha thrice daily, after having resisted all ordinary treatment.

CORRESPONDENCE.

To the Editor of the Philadelphia Medical Times:

Dear Sir:—The issue of the *Philadelphia Medical Times* for June 27 contains an editorial, the gist of which, the writer thinks, will not coincide with the convictions of the majority of medical men. The article, the exciting cause of which was an editorial in the *Medical and Surgical Reporter*, seems to premise that upon the occasion of an election to a professorial chair in a medical or scientific institution, the fact of a candidate being a son or close relative of the retiring occupant should carry considerable weight and influence with it.

Now, hereditary succession may do for the so-called "royal families" (royal families are notorious for mediocrity), but we hold that it is vastly out of place in those cases where the highest order of technical and professional erudition is demanded; and, admittedly, such is required of those who compose our faculties, the medical especially.

Professional calibre and attainments should be the inexorable and only measure of fitness of candidates for the high offices; and the object of this brief note is simply to call attention to this matter, and to protest against a species of family wire-working which has upon more than one occasion created dissatisfaction and enmity among medical men.

These remarks are to be taken in their general applicability, and have no special reference to the contest at the Jefferson College: in fact, the writer is not aware of any particulars regarding the vacancy at this institution, and the candidates and their prospects are equally unknown to him.

We all remember the commotion that was raised when Alexander Simpson stepped into the shoes of Sir James Y. Simpson. Let us see to it that no occasion arises with us for such a venting of spleen.

"Eupatorium Perfoliatum."

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

June 2, 1873.

Director W. S. W. Ruschenberger, M.D., in the chair.

Present,—Prof. J. Carson, and Drs. I. Norris, McQuillen, J. G. Hunt, Buckingham, B. H. Coates, Corlies, Holman, and Richardson.

Dr. J. G. Hunt made a verbal communication upon the histological appearances of the omentum, and exhibited some beautifully prepared specimens, stating, however, that he had found them some of the most difficult objects to manipulate he had ever undertaken.

Dr. Hunt also displayed a specimen of a stellate hair, or scale, from an ivy leaf sent to him in some vomited matter from one of our large hospitals, as a great

curiosity resembling the devil-fish described by Victor Hugo in his "Toilers of the Sea."

Dr. J. G. RICHARDSON narrated, as *apropos* to the case brought forward by Dr. Hunt, an occurrence which took place in his office that same afternoon, during a lesson he was giving a private student on the examination of blood. One of these stellate hairs managed to insinuate itself into a small drop of the circulating fluid, during an exposure of not more than three seconds elapsing between the puncture of the finger and the application of a covering glass, and the pupil very naturally remarked that had he found such an object under similar circumstances in his own experiments, he would have thought some wonderful discovery had dawned upon him.

Dr. HUNT said that the example related by the Secretary afforded a useful warning in regard to the caution with which we should receive the statements of such observers as Dr. Charlton Bastian, whose so-called investigations on the "Beginnings of Life" had been brought so prominently before the public. These momentous researches required a special and peculiar skill in manipulation, of which few were capable, and the case referred to by Dr. Richardson proved how easy it was for extraneous matters to gain access to fluids whilst being prepared for examination, in spite of all ordinary precautions. To him it seemed far more probable that the low organisms described by Dr. Bastian found their way into the fluids tested by some similar accident, than that they had been spontaneously generated after their germs were destroyed by a boiling heat.

Dr. RICHARDSON did not wish to appear as an apologist for Dr. Bastian, but would like, for the sake of even-handed justice, to call Dr. Hunt's attention to the fact that in many of Bastian's, Wyman's, and Pouchet's ingenious experiments, a whitish flocculent film appeared within flasks (hermetically sealed at 212° Fahr. and afterwards exposed, with their entire contents, to an equal or sometimes even a higher temperature, in a digester) *before any opening had been made in them*, and therefore without any possibility of their enclosed fluid being contaminated by bodies floating in the surrounding atmosphere. Subsequently, when the necks of the flasks were broken off, *visible particles* of this whitish pellicle were removed and examined beneath the microscope, where it seemed to him no very wonderful skill in manipulation was required to avoid error in deciding whether they were composed of mycelial threads and spores of fungi.

SELECTIONS.

BUNIONS.

DR. CHARLES H. LOTHROP writes as follows (*Boston Medical and Surgical Journal*, June 26, 1873): "In the explanation of my mode of treatment, and the apparatus used, it is not necessary to speak of the various pathological changes which have taken place before the bunion has come under the observation of the surgeon. It is sufficient to say that, in the natural formation, the inner line of the foot and great toe is nearly straight, while there is an interval of more or less extent between each of the toes. Now, in this affection, the toe has left the place of its nativity and is found sojourning in a foreign locality. The internal lateral ligament and abductor pollicis pedis muscle have become lengthened, while the external lateral ligament and adductor pollicis pedis muscle have become shortened. The flexors and extensors of the toe have also, to a great extent, become adductors, and the result of this abnormal condition is that, in either flexion or extension, there is an effort to a greater displacement and consequently to a greater distortion. Sometimes this takes place to such an extent that the toe may be seen completely overriding its fellow. At such times there is a very conspicuous displacement of the metatarsal bone inwards, while the proximal phalanx is pressed outward, producing an angle at the metatarso-phalangeal articulation, which separates to some extent the internal margin of the articular surface.

"A wide boot or shoe in the treatment of bunion is unquestionably necessary, but that alone will not elongate that already shortened condition of ligament and muscle; something more is requisite.

"The recommendation of Mr. Erichsen, the division of the tendon and the application of an under splint, is not practicable; besides, there is danger of inflammation, and, finally, of stiffening of the joint. The compulsory apparatus of Mr. Key, by means of a partition in the stocking, like the finger of a glove, and a partition fixed in the sole of the shoe, could not be worn for any length of time without producing pain, inflammation, excoriation, etc. The apparatus of Mr. Bigg has, as I have been informed by a manufacturer of surgical instruments in Philadelphia, proved a failure, and the manufacture of it has been stopped. Displacement of the toe is the obstacle to overcome. This cannot be done by violence without great suffering and distress to the patient, but can be surely and safely accomplished by gentle means. It is necessary that a large boot, shoe, or slipper, made of cloth or other light material, be worn during treatment. A cot, made of muslin or some soft firm fabric, is placed upon the great toe; one or more strips of adhesive plaster are placed upon and around the heel, the free extremities of which extend towards the free end of the cot upon the toe. The ends of the plaster and cot are then connected by means of a strong rubber ribbon, and the *persuasion* of the toe to return to its natural position commences.

"It is sometimes necessary to use other strips of plaster to retain the apparatus in position, one about the instep and one about the ball of the foot, while another is sometimes bound about the great toe and attached to the second, in order to keep each in proper position.

"The contractile power of the external ligament and adductor pollicis pedis muscle is overcome without injury. If they do not readily yield, then they may be partially divided by the operation of tenotomy without any dangerous consequences. The danger of inflammation of the joint, resulting from the violent replacing of the toe, is avoided. The antagonistic power of the internal lateral ligament and abductor pollicis pedis muscle is once more regained. The flexor and extensor muscles perform only their legitimate functions. The horrible distortion disappears, and your patient thanks you, with a grateful consciousness that you are, like Luke of old, 'the beloved physician.'"

REVIEWS AND BOOK NOTICES.

COLUMBIA HOSPITAL FOR WOMEN. REPORT BY J. H. THOMPSON, WITH APPENDIX.

The Columbia Hospital was established in March, 1866. We have never seen it; we confess, with a blush, we have never before heard of it; but if it be as much larger than other hospitals as its report is larger than other hospital reports, Columbia may well be proud.

To use mild language, the book is not wanting in self-assertion. With its broad sheets and wide margins, its large, clear type, its elaborate spaces, its four hundred and thirty pages of printed matter, encased in crimson boards, it seems to claim relationship as a sort of distant cousin to the Army Medical Circulars; for upon the "Columbia Hospital for Women" the bright sun of official patronage has risen, and has gilded its towers—if it have any—with a gleam of governmental gold and glory.

As no alumni cluster as yet around this young institution,—as the Honorable Secretary of the Interior and the clerks of the department could scarcely be expected to contribute articles of gynæcological interest,—the great bulk of the work has fallen upon the actual officers, and the text treats principally of cases occurring among its inmates. A short history of the hospital opens the volume (if we except a few loose prospecti of the "College of Obstetrics and Gynæcology," which we found in hiding between the fly-leaves). From it we venture to quote the following: "By comparing the reports of this institution, for the last two years, with the reports of similar institutions in other parts of the country, it will be found that in proportion to our fixed population we furnish gratuitously medical and surgical relief to at least twenty per cent. more patients than are relieved at the hospitals in New York, Philadelphia, and other large cities."

The medical world, both in America and Europe, is beginning to think that it has been relieving gratuitously far more than there is any need for. The point made, too, about "in proportion to our fixed population" is odd. Who would think, now, that Senators, Representatives, and lobbyists would make any great demands upon an institution devoted to gynæcology? It also seems inconsistent to talk in one place of "fixed population," and in another to state that so many beds are reserved for soldiers' widows and wives and the many strangers who come constantly to the national capital.

The statistics do, indeed, appear favorable. Thus, the number of in- and out-door patients for 1872 was 4576: of these 3708 were cured, 561 relieved, 21 died; the rest incurable, unknown, and under treatment. Assuming the same ratio of success in these, we get an average of one unsuccessful result in about eighty, and one death in about every two hundred and fifteen cases; many of these being cases requiring surgical operation. The air of Washington is proverbially pure.

The first article, by Dr. J. H. Thompson, is upon lacerated perineum, and contains much good work, giving a full account of thirty-four out of the fifty-three cases occurring since the opening of the hospital,—a larger number of cases, it seems to us, "in proportion to the fixed population" of Washington, than New York, Philadelphia, and other large cities could speedily produce. The various causes of laceration are gone into by the author, scarcely sufficient stress, it seems to us, being laid upon the effect of sudden descent of the shoulders surprising the momentarily relaxed perineum, and too much upon the use of the forceps, which certainly prevent more lacerations, in careful hands, than they cause in careless ones, unless the national capital possesses more careless obstetricians "in proportion to its fixed population," etc.,—a thing we should be very sorry to believe.

A paper on vesico-vaginal and recto-vaginal fistula, admirable in every way, follows; then one on displacements and diseases of the uterus, with cases, and operations for their relief, including amputations of the cervix. We have not alluded to the illustrations of this volume as yet, but on page 77 we come upon one, illustrating procidentia, which is a study in itself. It reminds us of the old puzzle of Rosamund's bower. We have tried in vain to follow the meanderings of the peritoneal folds, and give it up. This plate—No. VII.—is savagely copied from Savage, and the worst of it is that the indebtedness is acknowledged. In fact, the plates generally are not of a high order. We are early told that as anatomical delineations of the female perineum are wanting in most works, two are given, one from Gray, the other a copy of one published by Agnew in his well-known—but by the author unnoticed—paper in Pennsylvania Hospital Reports, vol. ii. We also would call Dr. Thompson's attention to the magnificent plates in Savage's work on the Female Pelvic Organs. Baker Brown's work, too, if our eyes do not deceive us, is laid under unrecognized contribution,—errors and all. While on the subject, we may call attention to Plates VIII. and III., as unique, if not specially artistic. The flattening of the thigh in the former is probably an atmospheric effect. We hardly like to suggest that the immense protrusion of cervix in the latter is due to loom,—a sort of mirage, in fact,—though after comparing the plate *from* Savage with the plate *of* Savage we are not confident of the Washington artist's ability to hold the mirror up to nature.

To return, however: a very striking case of cancer of the uterus treated by bromine is given in the article on cancer, p. 155. This article is very extended, being largely made up of citations from other authors. Concerning the part played by chronic metritis in the causation of cancer, we think that a study of the author's own arguments would lead us to a different conclusion from his.

On page 202, a case of removal of a crochet-needle from the female bladder is given, followed by an extended and interesting account of similar accidents, exhibiting considerable research. By an unaccountable oversight, however, the case reported by Dr. T. G. Morton in vol. ii. p. 46 of Pennsylvania Hospital Reports is omitted,—a case remarkably similar to the one on which the article is founded. On page 223 is given a case of extirpation of the parotid gland, and, a few pages on, one of removal of the third lobe of the thyroid gland. We scarcely see the connection of these with the rest of the volume,—diseases of the parotid and thyroid glands being, unfortunately, shared by the male sex.

On page 227 a case of impacted fæces diagnosed as ovarian tumor of two years' duration is given. In this, atropia was administered on the theory that it "relaxes the circular fibres at the top of the rectum." Whether the theory be correct or not, suppositories of $\frac{1}{18}$ grain of atropia nightly, assisted by compresses of stramonium infusion to the lower abdomen and matinal enemata of oil and water, proved successful,—the treatment lasting from May 2 to July 10. In this, as in another case given, diarrhœa had been a prominent symptom.

Articles on pelvic cellulitis and diseases of the rectum conclude this section of the report, and, so far as the work informs us, it is all, up to this point, from the pen of Dr. J. H. Thompson.

The report of the dispensary, p. 250, consists of an article from Dr. F. A. Ashford, section Diseases of Females, containing a table of 1612 cases, followed by a paper on metritis acute and chronic, and endometritis, extending over sixty-two pages, full of interest and well worthy of perusal.

The section Diseases of Children opens with a paper by Dr. S. C. Busey upon intermittent fever, 334 cases having presented themselves during the period covered by the report. Statistical tables showing the percentage of cases among white and colored, adults and children, and males and females, are given.

To one point we wish to call attention. Page 328, Dr. Busey says, "Except in children one year of age and

under, there is no absolute certainty of arresting the paroxysms unless from fifteen to twenty grains" (of quinia) "be given during the intermission." Emboldened by a considerable experience in the malarial diseases of children, we wish to protest against the indiscriminate following of any such rule. We are convinced that by following the same law in regard to the dose of quinia that we do with other drugs, we can arrest paroxysms *as certainly* in children as in adults, however certain that may be; *i.e.*, for instance, that three grains of quinia for a child between three and four years are as effectual as ten or fifteen grains for an adult; and we are not convinced by the opinions of Binz, Jacobi, and others, that immense doses are free from danger. We may add that the muriate of quinia possesses advantages, in Dr. Busey's opinion, in the cases of children.

Dr. Busey next treats of entero-colitis, cholera infantum, dysentery, and difficult dentition together, because, he says, they so run one into the other as to make definite division difficult. Page 331, "all have one symptom, increased frequency of the alvine dejections," and, again, "yet all admit that clinically it is impossible to determine with accuracy the pathognomonic differences," and on page 332, "if frequent and exhaustive serous and choleraic stools attended with rapid waste and collapse define and limit cholera infantum, . . . where can be classed that common form of simple diarrhœa not usually attended with fever or abdominal tenderness? Is not the distinction one of degree rather than kind?" To which we add for the author's benefit the query, Are Asiatic cholera and cholera morbus different in degree only, and not in kind? Are Asiatic cholera and the effect of a Seidlitz powder different in degree and not in kind?—and pause for a reply. We had always thought that cholera infantum, by its suddenness of onset, by its obstinate vomiting and rapid collapse, was a sufficiently marked disorder to be diagnosed as a rule. In fact, the author admits as much somewhat farther on.

In regard to treatment, we find a little of the same confusion as in regard to diagnosis, though the article is carefully written by one familiar with the literature of the subject, and is of great interest. We can agree with the author's condemnation of mercury and his confession of the inutility of vegetable and mineral astringents. His reliance is upon bismuth, opium, and the alkalies, especially bismuth, whose beneficial effects we suspect are more due to the opium and alkalies with which he combines it than to its own inherent powers. He considers chalk as the best antacid, and recommends morphia and sulphuric acid in atonic diarrhœa in which the above treatment has failed. The use of creasote, an exceedingly valuable remedy in cholera infantum, is not noticed by the author. In entero-colitis, suppositories of opium are preferred to liquid injections, and we could wish that he had given us his experience as to the dose to be employed in proportion to the age, the risk of opium in suppository, in infants, being very great,—it being exceedingly difficult to give enough without giving too much, and in managing suppositories the dose cannot so readily be gradually increased and watched as in giving it by the mouth. The suggestions as to diet are, in the main, good. The recommendation of "pure and fresh country grass-fed cow's milk," however, is unfortunately too much like the alchemical formula for the elixir of life, beginning, "Take a thousand pounds of pure gold." The practical fact about milk appears to be that in very many cases it is the provoking cause of cholera infantum in cities; that its withdrawal does as much good as the administration of remedies. Of course something must be substituted; and, notwithstanding the aspersions which have been cast upon the merits of beef-tea, we know no better substitute than it, the withdrawal of milk and farinaceous food and the use of beef-tea for a few days sufficing, in the majority of cases seen early, to arrest the disorder at its outset. Of course, in the face of chemical analysis, and the bugbear, incipient science, he would be bold who would continue it as sole article of diet for any considerable time. The infant stomach will often reject beef-essence, where it retains beef-tea.

Brandy and ammonia are advised in the collapse of cholera infantum, though how often they aggravate vomiting and fail to produce reaction all know. Nor have we found Huxham's tincture of any use until the disease is completely checked. In fact, sulphate of quinia with opium and nux vomica has been better borne, in our experience, than the tinct. cinchon. comp.

On page 360, in regard to the thirst accompanying diarrhœa and cholera infantum, Dr. Busey says, "This is generally more apparent than real. The child is not able to appreciate the difference between dryness of the mouth and fauces and the demand of the system for fluid." This want of mental acumen on the part of the child is also, strange to say, discoverable in adults under similar circumstances. Again, "Pure water should never be given." We think this a mistake. Pure, cool water given a little at a time is certainly no more injurious than unlimited draughts of its recommended substitutes,—rice-water, toast-water, or even the albumenized water,—all of which, as they cannot be made continually, are apt to deteriorate rapidly in freshness and purity. We feel some doubt, however, whether the author's condemnation of "pure" water be not a covert commendation of the impure. Certainly, if impure water is useful for infants, it is not difficult to get.

We have read the article following, also by Dr. Busey, "on the value of certain drugs in the treatment of bronchitis," but can come to no satisfactory conclusion about it. It is hard reading, because the author does not tell us early what he intends to prove. Suspense may keep one up through a long novel, but never through a medical article somewhat long and very dry.

The report of the Department of Diseases of Eye and Ear, by Dr. D. W. Prentiss, concludes the volume. All in all, this is the most thoroughly true hospital report we have ever seen. It shows an amount of faithful work of which any institution might be proud, and, while we think it will be difficult, on the same plan, to make succeeding reports come up to its standard, we hope earnestly that they may, and recommend the present volume to the careful attention of all interested in the subjects of which it treats.

GLEANINGS FROM OUR EXCHANGES.

Rare Dislocation of the Humerus (*British Medical Journal*, June 7, 1873).—A. W. Stocks reports a case of dislocation of the humerus, where the flattening of the shoulder and the prominence of the acromion, said to be common to all luxations of the humerus, were absent. He describes the case as follows:

"The shoulder at first sight gave no indication of any abnormal position of the head of the humerus. There was no undue prominence of the acromion, nor perceptible flattening of the deltoid muscle, conditions almost invariably present in dislocation of the humerus. The arm was capable of very extensive movements: it could be brought to the side, raised to a right angle with the chest, and extended forwards. The only motion which was restricted, and that to a slight degree, was the backward one. Of course, none of these movements could be accomplished without considerable pain. The

sole alteration in the figure of the joint was a slight flattening on its anterior aspect, rendering the coracoid process just perceptible to the eye, and a slight bulging under the posterior edge of the acromion.

"It will be remembered that in the normal condition of the shoulder-joint, when the arm hangs perpendicularly by the side of the body, the head of the humerus projects slightly beyond the anterior edge of the acromion process, and that there is a corresponding hollow or depression under the posterior edge of that process. A condition the exact reverse of this was the whole distortion found in this case."

The dislocation here was probably "sub-acromial," and the head of the bone rested on the posterior edge of the glenoid fossa. In considering how it was retained in such a position, he concludes:

"The only theory that I can offer is, that the long head of the biceps had become partially dislocated from its position, arching over the head of the humerus, and slipped down anteriorly to it, preventing its return into the glenoid fossa; whilst the tendon of the subscapularis, which is generally in backward dislocation found to be detached from the lesser tuberosity of the humerus, had not been ruptured, so preventing the further and more evident displacement of the bone behind the neck of the scapula."

Spontaneous Origin of Cholera.—In a very interesting account of cholera epidemics in South America (*American Journal of the Medical Sciences*, July, 1873) Dr. E. M. Estrazulas sums up as follows:

"1st. Cholera was unknown in Paraguay and La Plata previous to 1866.

"2d. Before the armies were stationed at Estero Bellaco, no case had occurred, and after the removal of the troops the disease totally disappeared.

"3d. No vessels from infected ports arrived at La Plata or Paraguay previous to 1866.

"4th. If cholera had been imported from abroad, the cities at La Plata ought to have been the first attacked.

"5th. Troops coming from Brazil could not have brought the disease with them, as it did not exist at any Brazilian port or city at the time.

"6th. Cholera appeared first in Paraguay, and following the course of the rivers infected in its downward march all the cities on their banks.

"7th. The disappearance of the successive epidemics followed an inverse route to that of the invasion.

"8th. The Paraguayan army, where the disease first appeared, was secluded from the rest of the world and completely blockaded by land and water.

"9th. The disease remained endemic for three years in Paraguay.

"10th. The combination of causes at Estero Bellaco resembled those presented in India.

"11th. The combination of causes in India has never been reproduced except in Paraguay."

Trigeminal Neuralgia treated with the Constant Current.—In *The Practitioner* for June, 1873, Mr. Samuel Craddock, F.R.C.S., reports a case of severe neuralgia of the left fifth nerve, in a neurotic patient, æt. 64, following exposure to cold and damp, and persisting for five months. Every branch of the sensory portion of the nerve became affected, and for eight weeks nothing but liquid nutriment could be taken, and that only through a glass tube. Alkalies were administered under the impression that the disease was due to the gouty diathesis; iron, arsenic, and nux vomica were given; hypodermic injections of morphia and atropia were employed; and finally, after the failure of these and many other remedies, the daily application of a constant current derived from eight cells of Weiss's battery was commenced. The positive pole was placed at the back of the neck, and the negative applied successively to the several foci of pain, being kept steadily on each for a minute or more. After the third application the improvement was marked and continuous, and at the end of a fortnight the cure was complete. The direction of the current here was "inverse," from centre to periphery; and this is one of many cases which seem to show that the older ideas regarding the influence of the direction of the current must have been to a large extent erroneous.

Use of Gelatin Suppositories in Obstinate Constipation due to Accumulation of Fæces in the Rectum.—In the above cases, and when there exists an accumulation of hardened fæcal matter in the rectum or colon, Dr. Nagel (*Allgemeine Wiener Med. Zeitung*, April 1, 1873) finds that when purgatives and enemata have failed, and in order to dispense with the use of the anal *curette*, suppositories of gelatin constitute an easy, harmless, and effective means of removing the evil. The suppositories are made of brown gelatin. They are steeped in water for twelve hours, and being thus softened and enlarged are introduced into the rectum. By subjecting the patient to a suitable regimen, an evacuation of pultaceous matter is obtained in twenty-four hours. The author attributes these effects to the hygrometric properties of the suppositories.—*Lancet.*

Nocturnal Incontinence of Urine cured by Chloral Hydrate.—Dr. Girolamo Leonardi has recorded in *Raccoglitore Medico* five new cases of the above, in which the use of a solution of chloral hydrate was entirely successful. The patients were all aged eight to ten, and the disease had resisted various means which had been previously employed. In all the cases the cure was effected most promptly, and was permanent. The dose was from seven to fifteen grains in about an ounce and a half or two ounces of water, taken at once or in two doses. In some cases the very first dose was successful, in others five doses were necessary to effect the cure. The drug was administered in the evening, two hours at least after food; and Dr. Leonardi strongly recommends that the patient should drink as little water as possible.—*Lancet.*

Enlargement of the Tonsils as a Cause of Nightmare (*British Medical Journal*, June 7, 1873).—J. Warrington Haward, F.R.C.S., relates some cases of nightmare occurring in children, resisting ordinary methods of treatment, and increasing in frequency and severity, which were at once permanently cured by the removal of a portion of the tonsils. As these glands were enlarged, he was led to believe that the obstruction to respiration and consequent cerebral congestion were sufficient to produce the disorder. Nightmare due to gastric irritation or dentition occurs, as a rule, only once in the night, while that due to enlarged tonsils often recurs several times in the same night, and is invariably observed to be aggravated by the child catching cold.

Fatal Poisoning from Chlorate of Potassa.—In the *Pacific Medical and Surgical Journal* for June, Dr. A. M. Ferris gives a case of supposed poisoning from chlorate of potassa, where a "large spoonful" of the salt was swallowed by mistake, and was followed by congestion of the surface, blue lips, cold extremities, inability to empty the bladder, hæmaturia, and death. At the post-mortem examination the auricles were found filled with large coagula, and the ventricles empty and contracted. The lungs and abdominal viscera were healthy. As the brain and kidneys were not examined, absolute proof appears to be wanting that the symptoms were really due to the salt of potash.

Delirium Tremens after Chloral-Drinking.—Dr. George F. Elliott (*Lancet*, May 24) relates an interesting case where the excessive use of chloral produced inaptitude for exertion, muscular pains in the upper extremities, loss of appetite, great thirst, constantly fetid breath, constipation, and finally a semi-comatose condition. The patient, a man æt. 35, had been in the habit of taking fifteen grains of opium daily for many years, but had for a few weeks substituted chloral, taking two hundred grains in the twenty-four hours. Its withdrawal produced at first sleepiness, and then all the phenomena of delirium tremens, which subsided under the use of large doses of tartar-emetic and opium.

MISCELLANY.

Making Mistakes.—If Liebig was hasty in expressing an opinion, he was equally ready to retract when convinced that it was erroneous. I once had a conversation with him on this point, and he spoke of the fear some scientific men had of being caught in a mistake. He considered errors inevitable and inseparable from the accomplishment of any scientific work; and it was on this occasion that he made the oft-quoted remark, "Show me the man who makes no mistakes, and I will prove to you that he does nothing." It is easy enough for a scientific man who publishes nothing, but only criticises others, to escape the charge of committing errors, and for such persons Liebig entertained a wholesome contempt. What he desired, above all things, to know, was the truth; and when he thought he had discovered it, he was anxious to give the benefit of it to the world.—*Journal of Applied Chemistry.*

The Cholera in Europe.—Reports from Dantzic state that on June 19, 27 cases of cholera occurring among Polish boatmen had been received into the hospitals at Neufähr and Strohdalch, of which 19 had died. The disease has reappeared in Warsaw, where from May 30 to June 12 there were 19 cases, of which four were fatal. Eight cases, of which five died, occurred in the neighborhood of Thorn on June 13 and 14. In Moravia, where no cases of cholera had occurred after March 23, the disease broke out on May 31 in a place in the district of Znaim. Six persons were attacked, of whom five died. In Galicia, during the second half of May, 118 new cases of cholera occurred in seven districts, with a population of 13,084. Including 48 remaining under treatment, there were in all 160 cases, of which 117 recovered, and 43 died.—*British Medical Journal.*

An Egyptian Medical Papyrus.—From the *Allgemeine Medizinische Central-Zeitung* we learn that Professor Ebers, of Leipsic, during a recent visit to Egypt, has obtained possession of an ancient papyrus, written in the oldest hieratic character, and believed to be above 3400 years old. Notwithstanding its great age, not a single letter is wanting in the hundred and ten leaves of which it consists. It is a complete treatise on ancient Egyptian medicine, in which the diseases of the several parts of the body and their treatment are described. Nine leaves are devoted to diseases of the eyes,—a subject in which the Egyptians were in advance of all other nations of antiquity. It is said that the King of Saxony has obtained possession of the papyrus for the library of the University of Leipsic.—*The Clinic.*

Medical Societies in Switzerland.—There are forty medical societies in Switzerland, including practitioners in all the cantons except Tessin and Wallis. The largest is the cantonal society of Zurich, with 149 members. One—the Oberaargau Medical Society—is more than a hundred years old; and five others have existed more than fifty years. About half of them hold twelve or more meetings in the year; the remainder meet less frequently—from one to seven times in the year. The cantonal society of Bern possessed a fund of 9500 francs at the end of 1871; the subscriptions to the others vary from one to five francs yearly.—*London Medical Record.*

Hygienic Use of Tea.—In a paper by Dr. Adam Smith, read before the London Society of Arts, the use of tea was recommended in the following cases: after a full meal, when the system is oppressed; for the corpulent and the old; for hot climates, and especially for those who, living there, eat freely, or drink milk or alcohol; in cases of suspended animation; for soldiers who, in time of peace, take too much food in relation to the waste proceeding in the body; for soldiers and others marching in hot climates, for then, by promoting evaporation and cooling the body, it prevents in a degree the effects of too much food, as of too great heat.

Quick.—They have rather a rapid way of living and dying in Memphis. Dr. Miller, of Atlanta, who was in Memphis while the cholera prevailed there, narrates a sprightly incident. At seven o'clock a man went to market and bought his breakfast, went home, cooked it, and was eating it, when he was taken with cholera. He sent for Dr. Miller, who visited him at nine o'clock, prescribed, and told him he would be back in an hour. At a quarter-past ten he returned. The man was not only dead, but had been buried, and the room swept and garnished for another occupant. What could Dr. Miller have given him?—*New York Tribune.*

Josh Billings on Doctors.—Doktors are not all quaks; yu hav got wrong noshuns about this.

Doktors, lawyers, and ministers hav a hard row to ho; they hav to deal with the kredulity, knavery, and fears ov the people, three ov the most difficult traits in human natur tew handle.

If i was a doktor, and understood mi bizziness, i should *doktor mi pashunts*, and let the disease take care ov itself.

More folks are kured this way than enny other.

It ain't much trouble tew doktor sick folks, but tew doktor the well ones is bothersum.

For upwards of forty years the ipecacuanha-plant has been cultivated in the Royal Botanic Garden, Edin-

burgh; but it is only recently that the plant has been propagated. The continued destruction of the ipecacuanha-plant in Brazil, and the risk of scarcity in the supply of this valuable remedy for dysentery in India, have called attention to the desirability of introducing its cultivation into the British possessions in India. Great numbers of the plant have, therefore, been sent from Edinburgh and extensively distributed in India.—*Medical Times and Gazette.*

An Application to Corns.—Castor oil applied to the corn, after paring closely, each night before going to bed. It softens the corn, and it becomes as the other flesh. It will cure every time.—*Southern Med. Record.*

Female Doctors.—The *Pharmaceutical Journal* quotes the following couplet from the "Nugæ Canoræ Medicæ," where the poet-laureate of the Edinburgh New Town Dispensary predicts,—

"An' when the leddies get degrees,
Depen' upon 't there's nocht 'll please
Till they hae got oor chairs an' fees,
An' there's an en' o' you an' me.
For a' that ken the woman craiter
Maun own it is her foremost faitur
To tak' to lecturin' by natur';
An' hoo she'll do't ye sune 'll see."

A Labelled Monarch.—The King of Dahomey is reported to have changed the fashion of his wearing-apparel. Seated on his throne, he received a scientific commission, not long ago, his body profusely decorated with the blue, gold, and green labels which had been carefully peeled from the medicine-bottles brought by Europeans into his dominions.

Indian Wit.—The Modocs seem to have taken a hint from their pale-face brethren, and are prepared to advance the plea of insanity in defence of Captain Jack. The distinguished murderer is reported to have conducted himself in the most approved fashion, sitting apart, plunged in moody thought, and unapproachable by his own relatives.

A Professor of physiology, in explaining to a class of female students the theory according to which the body is renewed every seven years, said, "Thus, Miss B., in seven years you will in reality be no longer Miss B." "I really hope I sha'n't," demurely responded the young lady, casting down her eyes.

To Prevent Glue becoming Sour and Mouldy.—The addition of a quantity of carbolate of soda, just sufficient to give a strong smell to the glue, will accomplish the desired result.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 8, 1873, TO JULY 14, 1873, INCLUSIVE.

Peters, D. C., Surgeon.—Granted leave of absence for thirty days, with permission to apply at Headquarters Division of the South for an extension of thirty days. S. O. 106, Department of the Gulf, July 1, 1873.

Retransferred from Department of the Gulf to that of the South, and on expiration of his present leave to report in person for orders to Headquarters Department of the South. S. O. 36, Military Division of the South, July 4, 1873.

Greenleaf, Charles R., Assistant-Surgeon.—Granted leave of absence for three months. S. O. 124, A. G. O., July 9, 1873.

Brooke, John, Assistant-Surgeon.—To repair temporarily to Portland, Oregon, and report to the attending Surgeon for medical treatment. S. O. 78, Department of the Columbia, June 24, 1873.

Phillips, H. J., Assistant-Surgeon.—Assigned to duty with troops about to march to the Columbia River. S. O. 76, Department of the Columbia, June 20, 1873.

Koerper, E. A., Assistant-Surgeon.—To report to the Commanding General, Department of the Lakes, for assignment to duty. S. O. 137, c. s., A. G. O.

Weekly Return of Deaths and Interments in Philadelphia for the Week ending Saturday, July 12, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE.

REMARKS ON CONCUSSION OF THE SPINE.

CASES OF SPINAL CONGESTION, WITH ONE AUTOPSY.

Reported by Dr. W. H. PARISH, from a Lecture

BY DR. H. C. WOOD, JR.,

Clinical Lecturer on Diseases of the Nervous System in the University of Pennsylvania.

CONCUSSION of the spine has, by writers, been divided into two kinds: primary and secondary concussion. The former term has been applied to a condition attended with symptoms which present themselves immediately after the reception of a blow on the back, or more generally of a fall, as from a scaffolding or a railroad-car. In this, the *true* form of concussion of the spine, there is no discernible lesion even to the microscope; yet there must be some disarrangement of the relations to each other of the minute nerve-structures of the cord,—a disarrangement which occurs at the time of the reception of the injury, and which is immediately attended with such symptoms as were presented in the following history of the patient now before us.

I. S. B., æt. 44, fell, on August 27, 1872, through a skylight, down, some thirty feet, to the floor. He was picked up in an unconscious condition, but recovered his mental faculties in about twenty-four hours. From the moment of the fall he was absolutely paralyzed in all those muscles dependent for their nerve-influence upon the spinal cord below the fourth or fifth vertebra. Although placed under no medical treatment, in three weeks he was able to move the toes of the left foot, and a few days later motion began gradually to return to the other extremities. In six months, still without medical treatment, the man was able to walk, though with decided lameness.

The above statements we gathered from the patient himself. On the 18th of March he was first seen by us. He then presented the following conditions:

His powers of locomotion were quite good, yet there was a lameness in his gait. There was no marked wasting of the muscles of the lower extremities. The grasp of either hand was less than normal: the right being somewhat better than the left. Since the finer motions of the fingers were impaired, he could scarcely pick up a pin. The arm could be flexed by the patient, but with apparently more than ordinary exertion. The biceps in each arm seemed to have lost much of its power, and there was tonic spasm of the triceps extensor. Both deltoids were evidently wasted. There were at times, also, pains along the vertebral column. To-day there is no change in these conditions, excepting some slight improvement.

At the time this man was picked up there was complete spinal paralysis, and the case was therefore one of spinal concussion; but that concussion has resulted in the production of some positive inflammatory lesion. I do not think there is softening of the cord-substance. When we apply the electrodes of the battery, you see that the deltoid, triceps, biceps, and, in fact, all of the arm-muscles, respond. This response shows that the nerve-cells of the cord cannot be destroyed, for were such the case the deltoid would not at all respond at this date, more than six months from the occurrence of the injury.

Were there softening, the paralysis would be considered beyond the reach of any remedial measure. Most probably there is slight sclerosis, with meningitis. By sclerosis is meant an inflammation of the connective tissue of the cord, attended with induration, and slow and chronic in its nature. The pain and muscular spasm indicate an inflammatory condition of the meninges irritating the nerves as they pass through those coverings. It has been stated that if there is chronic meningitis, the application of heat or cold along the vertebral column will be accompanied with more than the ordinary amount of pain. This test, when responded to, is of diagnostic value, but if it is not productive of pain we cannot say that chronic meningitis does not exist. In this instance, as you now see, this test gives no response.

We have instituted the following treatment for this patient. He is taking the iodide of potassium in liberal doses, one drachm three times daily, after meals. If the remedy produces much nausea, headache, or its characteristic eruption, it is to be suspended for a few days, but to be renewed and persisted in. It would be trifling with our patient to administer this remedy in five- or ten-grain doses. Counter-irritation along the spine is to be employed. For the muscles we have directed kneading, friction, and faradization, with passive exercise. To the contracted muscles is to be applied belladonna in some form, either by rubbing in the ointment, or, by what is better, the hypodermic use of atropiæ sulph. This remedy, by diminishing the power of nerve-structure to convey nerve-influence, is our most efficient agent in the relief of spasm. Of course good diet, fresh air, and medicinal tonics, as called for, are not to be neglected. I believe our patient can be cured if such a course is faithfully persisted in.

Under the head simply of concussion, or sometimes of secondary concussion, of the spine, have been described numerous cases, which, from their frequency in railroad-accidents, are assuming great importance. Especially is this true since they are very frequent subjects of legal inquiry, owing to the institution of suits for damages by the injured parties. In these cases the symptoms do not develop themselves at once. Often has the subject of this affection extricated himself from the *débris* of a wrecked train, assisted those about him in getting free, spent hours, perhaps, in relieving the injured, and congratulated himself that he has escaped injury. Days, weeks, or months after the injury, the symptoms of deranged innervation come on, perhaps most insidiously, and progress until the sufferer is as much a wreck as the fated train itself. The chief point I want to call your attention to to-day, is that these cases are not cases of concussion,

but are really instances of traumatic inflammation or congestion of the cord, and have no more right to the name by which they are generally known, than has an abscess of the brain from external violence to that of concussion.

The relation between these cases and those of true spinal concussion is, indeed, almost precisely that between cerebral concussion, with its sudden suspension of consciousness, and that of latent abscess of the brain from a blow, with its slow and insidious development of symptoms.

There is now under our care at the Philadelphia Hospital a patient whose history will present you a case of this so-called concussion of the cord. It is as follows:

Thomas S., æt. 35, of good general health, fell, on March 6, 1873, through the opening in a coal-car while dumping it, and alighted on his feet. The accident was accompanied with some pain in the small of the back, but the man was able to walk home,—some two miles. He was admitted to the hospital on March 8, being, however, able to walk a considerable distance. On the 9th he noticed that his legs were weak. On the 10th there was increased weakness, with numbness and pricking sensations in the feet and legs, and to a slight extent in the left hand. There was also pain in the lumbar region. On the 14th the aching pains and numbness in both legs had increased; the left being more affected than the right. The patient was entirely unable to stand; and so complete had become the paralysis of the lower extremities that he could not raise his knees from the bed. The flexor muscles seemed somewhat less involved than the extensors. No anæsthesia.

No distinct loss of power in the upper extremities. At night there was some shortness of breath.

He was ordered ext. ergot. fl. ʒss; fifteen ounces of blood were taken from the margin of the anus by leeches.

On the 15th the pains had disappeared.

March 20.—Slight improvement since last note. The knees can be slightly raised from the bed. Has not had an erection of the penis since his admission.

To-day began the use of a continuous current along the spine daily, and faradization to affected muscles on alternate days. Friction, kneading, and shampooing of the lower extremities with lin. saponis are also to be resorted to.

March 25.—Ext. ergot. fl. increased to fʒj *ter die*, without being productive of any unpleasant symptoms save a little nausea. Motion in legs a little improved.

Now, gentlemen, what is the true pathology of this case? Evidently, it is not right to call it concussion. Evidently, if there is not to be an endless confusion in the nomenclature of nervous disease, this affection is to be called a traumatic lesion of the spinal nerve, precisely as a similar affection of the brain similarly produced would be spoken of as a traumatic lesion of the cerebral centres. But can we not define more particularly what the lesion is? Certainly. You will remember that in a lecture delivered some time since I told you that there is an acute affection of the spinal nerve, which is clinically distinguished by the gradual but rapid and unequal development of a creeping paralysis, affecting the legs in most instances more than the arms, by the absence of febrile reaction or of severe pain, and by the presence of numbness, and of a feeling of "being asleep," or of prickling, in the affected limbs. I told you also that this disease was produced by a variety of causes, among others by exposure to cold, by lying upon the back on cold ground, by fatigue, and by a "wrench of the back." In regard to its pathology you were told that post-mortems are very rare, there being very few on record, but that the lesion is without doubt a congestion of the vessels around and pressing upon the cord, and a consequent exudation of serum into the canal. Since that lecture I have had a fatal case; and I lay the history before you, to show the similarity of the symptoms with those of the traumatic case, and afterwards I will read you an account of the autopsy.

Frederick L., æt. 40, and a native of Philadelphia. From his own statements we learn that his parents were healthy; that he has never been addicted to intemperance in drinking, nor to excessive venery; he has never had a chancre; has several times fallen from giddiness, but was never afterwards confined to his bed; for several years he kept an employment office in this city. He has been in the Philadelphia Hospital on two previous occasions, suffering only with general debility.

About one year ago there were sensations of numbness and tingling in the fingers and toes, but, though weak, he was able to continue walking around. This condition lasted about one week, when the symptoms disappeared.

In June, 1872, he last applied for admission to the hospital, and was then assigned to the out-wards, his only complaint being that of feebleness. In these wards he did the work of a waiter in the dining-room. In this capacity he was willing and efficient, but for several days prior to being confined to bed he spoke of a feeling of numbness in his legs, which sensation he said was creeping upwards from his feet.

On the morning of October 7, on getting from bed and attempting to stand he found his legs unable to hold him up. Accompanying this loss of strength there was a sensation of numbness and tingling in his feet, and also in his hands, as if they were asleep.

"October 11, 1872.—To-day he was transferred to the hospital proper. When taken into the ward, about 3 P.M., he was able to stagger a few steps, the nurse stoutly supporting him. While sitting on a chair he was able to remove his own stockings.

"October 12.—The man thinks there is no impairment of his mental faculties; yet he seems easily affected, readily shedding tears. He passed his urine last night involuntarily. On getting him out of bed, his legs were found utterly unable to support him. The arms also seemed weak. He said there were marked tingling and sensations of 'pins and needles' in the right hand and in the feet and legs. The left arm having been amputated below the elbow years previously, there was no alteration in the usual sensations of the stump. An induced current caused only feeble contractions in the muscles of the legs and of the arm. There was also marked loss of electro and general sensibility in the extremities. The bowels were constipated.

"October 13.—The loss of muscular power evidently increasing; and especially is this observable in the upper extremities. To-day he was ordered fifteen dry and six wet cups, to be applied along the entire length of the spinal column, and also to receive an effective dose of castor oil. In a few hours the bowels were freely moved.

"October 14.—The symptoms seem to have undergone no change since yesterday, excepting that he is less able to retain the contents of his bladder, and his

arm has become so weak that he is no longer able to feed himself.

"October 15.—The man has some cough, and states that for the last two nights he has, at times, had a great deal of trouble about his breathing. Posteriorly his chest is full of sonorous râles. The heart-sounds are normal. He cannot now, without assistance, get his arm from under the cover.

"October 18.—Since the 15th there has been complete loss of control over the bladder, the urine dribbling away and not distending that viscus. The bowels have again become constipated. There is not absolute loss of all power in the lower extremities, but they are so very feeble they cannot be at all raised from the bed, and can be wabbled only a little. There is a similar, but less prominent, condition of the arms.

"The respirations have become exceedingly full, deep, and labored, numbering seventeen per minute. The pulse, though somewhat feeble, is quite normal. There are no febrile symptoms. Both lungs are filled with coarse sonorous râles. The sputum is somewhat purulent and bronchitic. His voice is exceedingly weak and husky, even whispering, but there is no laryngeal pain or soreness. The anæsthesia, though very marked, is not absolute. Reflex action in the legs is much diminished. The muscles of the legs respond but very sluggishly to a strong current of the second coil.

"8 P.M.—Respirations have become gasping and very feeble, but very labored. He has an anxious, distressed expression, and complains much of dyspnœa, saying that he is suffocating. These symptoms become aggravated if he is not kept in a semi-erect position. He has not been able to swallow for several hours. Being given a spoonful of milk, he was unable to swallow it, and the attempt brought on a fit of choking and intense dyspnœa.

"About half an hour afterwards he died, without presenting any additional symptoms, his mind remaining clear to the end.

"During no period of the attack have there been pains or other symptoms of rheumatism, nor was there a prior history of this affection. There have not been any convulsions or tremors of any kind; no rigidity of the muscles, no delirium, and no coma."

As I have read this case, no doubt you have perceived the resemblance of the symptoms with those of the man who was injured in the coal-car, and noted that the differences are simply of degree, the most important arising from the cord being involved higher up, in the last case. Let us now look at the autopsy, and then I think you will agree with me that our other patient is suffering from traumatic congestion of the cord, probably with a small amount of effusion.

Autopsy, fourteen hours after death.—On exposing the dura mater of the cord, the veins beneath it were seen to be much congested, and on pressure along the cord there was a distinct wave of the serous fluid within its membranes, this being evidently much increased in quantity. There were no bright spots of injection on either the cord or its membranes. There was no exudation of lymph nor other evidence of inflammation. The veins of the medulla were enlarged. The rest of the encephalon and its membranes seemed healthy.

Both lungs were much congested. The other thoracic and the abdominal viscera seemed quite normal. The kidneys were examined microscopically by Dr. R. M. Bertolet, who kindly made the following report:

"The kidney of the spinal case did not present any infiltration of the interstitial tissues, nor thickening of the tunica propria. The epithelium of the tubules was, however, swollen and cloudy from the deposition of granular matter in its protoplasm. Could easily see the nuclei upon the addition of acetic acid. This cloudy swelling does not positively indicate a hyperæmic condition of the organ during life, since it may be merely a post-mortem change."

It would be foreign to my purpose to say much about the treatment of congestion of the cord. Suffice it to point out that death occurs by a gradual increase upwards of the congestion, by a gradual rising of the exudation and consequent involvement of the respiratory nerves, which the most active measures may fail to prevent; and that the best treatment is free local bleeding from the neighborhood of the anus, the use of dry cups over the spine, and the exhibition of large doses of ergot (f℥ss to f℥j); after a time electricity may be used, especially in the form of faradaic currents, to maintain the life of the muscles affected.

[Under the treatment noted, the traumatic case made a good and rapid recovery, and in a few weeks left the hospital, well. He suffered no inconvenience, save some headache from the use of three fluidounces, daily, of the ext. ergot. fl.—H. C. W., Jr.]

The following case, occurring in my private practice, will serve to illustrate another form of traumatic spinal affection constituting a variety of the so-called concussion of the spine, besides being of no little interest as presenting such distressing and varied sensory illusions.

Mr. T., æt. 40, a gentleman of temperate habits and good health, fell on his door-steps, striking with great violence across the lumbar region. Considerable pain and stiffness ensued, but no trouble beyond what would be expected. He attended to business as usual, and appeared to be recovering from the effects of the fall. A few days subsequently, however, while lying on the bed and engaged in reading, he was surprised by a sort of spasm of the genital system, followed by an ejection of semen. In two or three days this happened again. These experiences were entirely disassociated with sexual thoughts or excitement, and were very distressing. A few days later, and when the more immediate effects of the fall had quite disappeared, a business trip to New York and Boston was undertaken. The motion of the cars, and subsequently of the boat, produced a most tantalizing discomfort in the genito-urinary system,—a mixture of sensations referred in part to the bladder and in part to the seminal tract, a disposition to urinate, and a feeling as of orgasm prevented. The whole nervous system seemed as though transformed into a genito-urinary apparatus. Involuntary spasmodic movements, as of orgasm, continued and increased in severity, without erections, until they resembled the efforts of a dog in vomiting. In this way the night was spent, sleep being impossible, although some slight relief was obtained by sitting in a basin of cold water. During the next few days the same symptoms occurred at intervals, lasting from one to three hours; the intermissions being intervals of absolute freedom from them. After the lapse of ten days the return trip to New York developed them in all their horrid intensity. In New York getting a night's sleep, he felt the next morning a sense of elasticity and sprightliness which was unusual for him even when well. But the ride in the cars from Jersey City to Philadelphia again developed the symptoms to such an extent that sitting still was not to be thought of, and the time was spent in the water-closet in vain efforts to obtain relief by pressure, by constant at-

tempts at urination, etc., although the bladder was empty. Reaching home almost crazed by the irritation, which had now become constant, his strength was so far exhausted that he was just able to crawl up-stairs and into bed. The hyperæsthesia extended to the rectum, to the thighs, to the abdomen, and to the back. Sensations as of an evacuation of the bowels, of the bladder, or of seminal emissions, were constant. Sometimes the parts felt as if exposed to a hot fire, and the skin covering them would seem as if it would break from dryness when bent. These sensations would alternate with those of such an exalted sensibility of one part or another, or of all the surface from the waist to the knees, that contact with clothing was torture almost enough to drive him mad. Then would follow relaxation, accompanied with a dreadful feeling of absence of vitality,—to the consciousness, not to the touch,—and local sweats which were marked by a peculiar acid odor. With all this there were feelings as though the urethra was being tickled with a feather; as though seat-worms were passing in and out of the rectum; as though the scrotum was made of wires which were being twanged, or of tubes through which water was flowing. Every sensuous thought had to be avoided: an exposure of a female leg on the street would almost cause a tetanic spasm. This condition of things lasted for more than three years, with intermissions or modifications of one, two, or three days, every two or three weeks. In these intervals sexual relations were normal, and always followed by relief, and even sometimes were sought only because of the relief afforded. At other times sexual thoughts provoked a hyperæsthetic condition of the genital system, on which such an intimation acted as water is supposed to act on a mad dog. At no time was there priapism, and at no time a loss of power, but at times a sensitiveness which could no more bear a sexual thought than an inflamed eye could bear the noonday sun. On one of these occasions the touch of a female's hand was so acutely and intensely painful to these sensibilities that she was entreated to leave the room instantly.

During the first three years alluded to, various other anomalous and distressing symptoms appeared with more or less frequency, as though he were trying to walk with a large, soft ball—as of a cocoanut in size and a soft orange in consistency—held between the thighs, or of a wad of cotton pressed tightly between the nates; of a twisted condition of the muscles of the legs, which twisted tighter at every step; of his drawers having become unfastened at the waist, and dropping down entangling his legs; of the feet being cushions; of the pavement giving as it does when the frost is coming out of the ground; of the feet being buried in sand or grain; of draughts of air and flowing of water from the feet upwards; of still walking after stopping in a walk; of being lifted in the air by the effort at defecation, or in response to a sneeze or cough, or an ejection of flatus; of the chest being bound in hoops; of the muscles of the perineum being grasped from within and raised and twisted; of being lifted from the bed and floating in the air. Sleep always afforded relief. Ale would also bring relief; though sometimes large quantities were required. No medicine seemed productive of any good.

Nearly seven years have elapsed since his fall. There has been a gradual improvement, with the exception of aggravations from unusual mental or physical exertions, or from changes in the weather.

The pathology of this case, gentlemen, is, I believe, one of chronic congestion, or possibly slight nutritive changes, of the nerve-cells,—chronic irritation, if you like the term, involving the posterior or sensory portions of the lumbar cord; strictly localized, and not affecting the motor centres.

Be this as it may, the case illustrates the point of the present lecture, namely, that chronic nutritive changes are the real lesion in the so-called concussion of the cord.

This idea is not a new one at all. Abercrombie and others recognized full well the truth that injuries produced chronic spinal inflammation. It has been reserved for modern times to speak of these cases as concussion of the cord; and, as a false name will often beget a false idea as to pathology, it is against the use of the term at present customary that I desire to protest. Remember, it is not merely congestion, as in the case described today, it is not merely chronic spinal meningitis, as in cases reported by Sir Astley Cooper and by Abercrombie, but any form of spinal inflammation, acute or chronic, that may arise from injury. Recognizing the true nature of these cases, you will have no especial difficulty in their treatment. Time will not allow me to go into details upon this point, but it evidently follows from what has been said that each case should be treated independently of its cause, precisely as would a similar spinal affection arising from any non-specific source.

ORIGINAL COMMUNICATIONS.

SOME CASES FROM MY OBSTETRICAL NOTE-BOOK.

BY H. E. WOODBURY, M.D.

CASE I.—Twin conception—Loss of one fœtus in the third month, by abortion—Delivery of the other still-born, in the eighth month, by version.—In the latter part of 1868, Mrs. B., a lady of prepossessing appearance, called to consult me relative to "a very peculiar state of things," and set forth her case as follows: "I am the mother of two children, both living. About two months ago, being in the third month of pregnancy, I had an abortion. I know the child came away, for I carefully examined it, and it was about the size of my forefinger. I kept very quiet in bed for some days, and suffered no inconvenience worthy of mention from the event. During the last week or two, I have felt frequent and distinct movements, as a woman does when she has quickened. I have consulted two of our most experienced physicians, and they assured me that if I had miscarried so recently I could not be pregnant, but that I was suffering from a nervous affection resulting from the miscarriage. Now, doctor, I have called to see you, because I am not satisfied as to my condition. Is it not a strange case?"

I remarked that while it might seem a strange case to her, to me it was a plain one,—one of rare occurrence, but one, nevertheless, that may, and sometimes does, occur. "To state it briefly, madam, you were pregnant: it was a twin conception; you lost one fœtus by abortion; the womb contracted kindly, and retained the other intact. This second fœtus quickened in due time, and you now feel its movements. At term, if not before (if your statement be correct), you will have satisfactory confirmation of my diagnosis in your case."

She expressed herself as satisfied with my solution of what had seemed to her "a strange enigma," and complimented me upon my readiness in unravelling the mystery.

The same evening her husband called on me. He stated that I had relieved his wife of much anxiety, and desired to know upon what grounds I based my opinion of her case. Had I ever met with such a case? I informed him that I had not; but, taking Ramsbotham's "Obstetrics" from my bookcase, I turned to page 585, and read, "Numerous cases are on record where one [*i.e.*, fœtus] has slipped away, as it were, during the early weeks of pregnancy, being expelled with scarcely any uterine effort, and another has been carried on to maturity." "I am sure that is her case," he remarked; "and we shall give you a chance to confirm it."

Time wore on, and I had not seen the parties for three months, when one day a messenger came for me in haste to attend a lady in labor. I obeyed the summons, and, on entering the lying-in-chamber, recognized the lady who had consulted me three months before. "You were right, doctor," she said; "and I would not let any one but yourself take care of me, for I anticipate a hard time, as it is premature." In this she was correct; for, after having been in labor forty-eight hours (with hard pains much of the time), the os was only dilated to the size of a shilling-piece, and the pains ceased from sheer exhaustion. The os was hot, dry, and unyielding. In this crisis, having lost much sleep during the two nights I had passed with her, I deemed it best to have counsel and assistance in the case. One of the physicians whom she had consulted previous to calling on me, met me in consultation. We determined to give chloroform, dilate the os, and deliver by version, at once. This was done; the child being still-born. On the morning of the third day after delivery, the mother had four or five convulsions. These yielded promptly to treatment,—viz., heroic doses of tinct. gelsemini; two doses sufficing to check them entirely. From this time she made a good recovery, and soon after left the city. I have since learned that she gave birth to a living child about two years after her former confinement, and that the labor was normal and of short duration.

Case II.—Twin conception—Abortion—One fœtus retained four days after the expulsion of the other.—In May, 1869, Mr. P. came for me, in haste. His wife, being in the third month of pregnancy, was taken, at an early hour in the morning, with violent pains, as of labor. I found that his apprehension of an abortion was well grounded; and in two hours after my arrival a small fœtus was expelled. A digital examination was now suggested, in order to ascertain if everything had passed and if the os was contracting. From hypermodesty on the part of the patient, this was refused. It is my rule never to leave a patient under such circumstances without first having assured myself, so far as is possible, that all is right. My rule was broken on this occasion.

Calling the next day, she informed me that she had suffered very much from "after-pains," but still refused to be examined. I prescribed a few grains of Dover's powders, and left.

On the fourth day she said to me, "Doctor, we have a good joke on you." I rejoined, "Perhaps the joke is rather on yourself: it surely is, if you have expelled another fœtus." She then produced, in a napkin, a fœtus nearly twice as large as the first one, saying, "It came away about two hours ago." I gave her a short lecture upon her duty to her physician, as well as to herself, referring to the fact that if she had permitted me to perform my entire duty she would probably have been relieved of the "after-pains" she had suffered for more than three days, and not have incurred the risk of a hemorrhage that might have occurred, although it did not in her case. Her recovery was rapid and complete.

Case III.—Retention in the uterus of a portion of the placenta for about one year.—Mrs. M., one of my patients, went home (to New York) in order to be under her mother's care during her confinement. She was absent about three months, and on her return her husband desired me to see her, as she seemed to be suffering from the effects of her confinement. Being anæmic and evidently debilitated, tonics and chalybeates were prescribed. Five months after the birth of her child the catamenia appeared, and her general health seemed much improved. She was regular for about three months, then ceased to menstruate, and believed herself to be pregnant. Pain, nausea, malaise, and nervous excitability were prominent symptoms in her case. There was enlargement of the abdomen, and she appeared like a woman three months pregnant. She suffered so much that I finally concluded to examine with the sound and ascertain if such was the case. I was truly astonished when, notwithstanding the almost unmistakable indications of pregnancy, the sound passed freely, not meeting with any obstruction for a distance of more than two inches into the cavity of the womb. I assured her she was not pregnant, but confess that the discovery of this fact puzzled me.

Surmising that this might be a case of polypus uteri, I prescribed liquor of ergot, in order to force some portion of the tumor into the cervix, and thus clear up my diagnosis. This was faithfully taken until its full effects, as evidenced by the pains resulting from contraction, were established. At this stage I concluded to suspend all treatment for a season, and rely upon the expectant plan. Three days later a mass passed from her, which she sent to me for examination. It was of the size and shape of a hen's egg. Passing through its centre, lengthwise, was an opening about the size of a small goose-quill. The outer surface seemed to be membranous. On making a section of it, my opinion that it was a portion of the placenta and membranes retained at the time of labor was greatly strengthened.

In reply to my question, "Did you notice anything peculiar in your last labor?" she said, "On the third day after delivery, something hanging from the vagina annoyed me, and, taking hold of it, I tried to pull it away. This gave me great pain; so I desisted, and soon after noticed that it had disappeared." She further stated that the after-birth seemed much smaller and passed more readily than in her former confinement.

The facts and circumstances in this case justify me in arriving at the following conclusions, viz.: that a portion of the placenta and membranes was retained, and adherent at some point just inside the cervix. That pulling upon the membrane caused rigid contraction of the cervix, and consequent retention of the mass, moulding it to the shape of the uterine cavity. When the menstrual flow was about to return, she suffered from the symptoms of suppression, until an outlet was furnished by means of the canal found passing through the centre of the mass. That the subsequent obstruction to the flow resulted from a change in the position of the mass, or closing of its upper orifice. That the ergot caused the final separation and expulsion of the mass. Her recovery was perfect.

WASHINGTON, D.C., June 28, 1873.

ANÆSTHESIA.—M. Spessa has been enabled to cauterize, in coxalgia, with Vienna caustic, also to incise a fistulous canal in the neighborhood of the sternum, without producing any pain, by previously making a subcutaneous injection, near the part, of a solution of sulphate of morphia.—*Jour. de Méd., de Chir. et de Pharm. de Bruxelles.*

PARASITIC SKIN DISEASE CURED BY THE APPLICATION OF SULPHITE OF SODA.

BY FRANCIS L. HAYNES, M.D.

TINEA SYCOSIS.

CASE I.—December 8, 1872, J. R., aged 35, car-driver. He states that he contracted the disease at a barber-shop where he was shaved two months since. A customer of the same barber was at that time suffering from a similar disease, and two more have been attacked by it since. A few days after his visit to the barber's he noticed the appearance of red, itching spots around the hairs of the beard; after about ten days, dry, white scales began to form on these spots; a week since he used an irritating wash, which has greatly aggravated the disease.

Present condition.—The upper lip is quite swollen, and very tender. On either side is a large, white, prominent tuberous elevation. The remaining surface of the lip is covered with yellowish-white crusts, through which pass short brittle hairs, which are readily extracted by the use of the forceps. Hairs of the same description are scattered here and there over the elevations.

On microscopical examination, the hairs at and near their bulbs are found to be occupied by articulated and solitary conidia of tricophyton.

The patient was directed to keep the part constantly moistened, by means of pieces of old linen, with a saturated solution of sulphite of soda in water.

I did not see him again for six months, when his lip presented no appearance of disease, and was covered with a fine growth of hair. He stated that the use of the sulphite had removed the disease in about two weeks, and that the hair had immediately commenced to grow on the bare spots.

Up to the present time (June, 1873) the disease has not recurred.

TINEA SYCOSIS.

Case II.—J. H., aged 50, shoemaker, applied to me on December 1, 1872, suffering from a very aggravated attack of sycosis of two months' standing. Large white tuberosities, hard and very sensitive, were scattered here and there over the parts usually occupied by the beard and moustache. Yellowish-white scales occupied the intervals between the tuberosities. No traces of hair could be found on the affected parts. The disease had appeared shortly after the patient had been shaved by a barber. He was directed to use the same treatment as the above case.

December 3.—Greatly improved.

December 28.—The disease has nearly disappeared. One crust, four lines in diameter, and two or three pin-head tubercles, are all that remain. Continue treatment.

January 11, 1873.—One non-inflamed tubercle remains on the base of the chin. No appearance of hair. Discontinue treatment.

March 18.—Saw the patient for the last time. No traces of disease could be found. The beard was growing vigorously.

TINEA TONSURANS.

Case III.—January 30, 1872, H. O., aged 3, female, has had ringworm of the hairy scalp for six months. It is supposed by the relatives that she contracted the disease from a playmate who was affected by it.

A diseased spot one by one and three-fourth inches in extent exists on the vertex; another, two and a half by one and one-third inches, over the right ear. Both are covered by dry, friable, dirty-yellow crusts, two or three lines thick, through which protrude a few straggling deformed hairs. On microscopic examination, numerous tricophyton conidia were discovered in the crusts and hairs covering the spots, also in the hairs immediately surrounding the spots.

The parents are directed to apply poultices continuously for two days, in order to remove the scabs.

February 1.—The poultices having proved ineffectual, the crusts are removed by the scissors, and the hair cut short over the entire scalp.

Treatment.—Apply poultices for twelve hours, then a saturated solution of sulphite of soda. The solution is to be used in this manner: A cap is to be made from old linen, which, after being moistened with the solution, is to be applied to the head. A second cap of oiled silk is to be superimposed, to prevent too rapid evaporation.

February 3.—Much improved. Spots very clean. Healthy hair beginning to grow in them. Continue.

February 11.—No appearance of disease. Hair growing vigorously. Discontinue treatment.

The patient had no return of the disease for six months, when, on a second exposure, she contracted it again. A repetition of the above treatment was followed by a speedy cure.

TINEA TONSURANS.

Case IV.—January 12, 1872, Peter C., aged 2 years, was brought to me, together with his three sisters. About two weeks ago a small moist spot appeared on the scalp. At the present time a diseased spot one by one and a half inches in extent exists on the vertex; it is covered with crusts, through which protrude a very few hairs. Scattered over the scalp are numerous similar spots of small size. The hairs on the diseased spots are short, brittle, and crooked; they can be extracted very readily, and without causing pain.

On microscopic examination of the diseased hairs, they are found to be irregular in outline; here and there the fibres are split; the ends are frayed out. They contain numerous conidia of tricophyton tonsurans.

Case V.—Mary C., aged 5 years, was attacked at the same time.

Case VI.—Anne C., aged 7 years, was attacked two months since.

Case VII.—Maggie C., aged 9 years, was attacked one month since.

All these cases presented the same symptoms, and the appearances of the diseased hairs were characteristic in all of them.

The same treatment was used as in Case III. The progress of the cure was slow, on account of want of care in keeping the solution constantly applied, and the absence of all attempts at cleanliness.

In two months, however, the disease had entirely disappeared in all the cases, and the hair was growing finely over the entire scalp.

THE URINE IN ADDISON'S DISEASE (*Revue des Sciences Méd.*).—Rosenstein reports in *Virchow's Archives* (No. 142) the results of the analyses of the urine of two patients suffering from Addison's disease. These analyses were made daily for two months, and always showed a considerable diminution in the quantity of urea excreted,—from twelve to twenty grammes in the twenty-four hours,—and a notable increase in the quantity of indican, which rose up to eleven or twelve times its normal amount.

NOTES OF HOSPITAL PRACTICE.

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,
Of Philadelphia.
Reported by J. Ewing Mears, M.D., of Philadelphia.

(Continued from page 661.)

CASE 242.—*Multilocular ovarian tumor; slight adhesion; incision five inches long; recovery.*

September 27, 1871, Dr. Atlee visited Florence, Alabama, for the purpose of operating on Miss T. K. She was 37 years old, and first menstruated at the age of fifteen years, having always been regular in every respect. Although rather delicate, she has always enjoyed pretty good health.

About two years before, she was aware that her clothing was becoming tighter about the waist. In January, 1870, she was seized with a severe pain extending from the breast to the pubes on the left side. This attack was repeated in May following. She supposed it to be an attack of indigestion, and went to Bailey's Springs, nine miles from Florence, under the care of Dr. Moody, and thought she was benefited. The menses were regular until June, 1870, when they were suspended until the spring of 1871, and after a return in March they were again suspended.

In October, 1870, Dr. H. A. Moody, of Bailey's Springs, tapped her, removing eighteen pints of opaque, thick fluid, darker than chocolate, which, after standing some time, adhered to the bucket on being poured out. After the tapping a tumor was discovered in the left hypochondrium and side, resembling an enlarged spleen in character and location. The tumor filled up the left side, and was thought to be an enlarged spleen.

The abdomen was pretty uniform in shape, and much larger than at full period of gestation. The only resonant point on percussion was over the left side and hypochondrium. The solid deposit in the region of the spleen seemed to have been transferred towards the right side. Fluctuation was more or less distinct, but interrupted. The pelvis was free; uterus central and movable, and admitted the sound three inches.

Diagnosis.—Multilocular ovarian tumor.

Drs. J. T. Hargraves, James W. Stewart, John M. Hays, John Lorence, and H. A. Moody, assisted in the operation. The patient recovered.

Case 243.—*Multilocular ovarian tumor; extensive parietal, omental, and hepatic adhesions; incision five inches in length; recovery.*

September 23, 1871, Dr. Atlee examined Mrs. J. S., of Edina, Knox County, Missouri. She was 27 years old; first menstruated at the age of fourteen, and had always been regular. She was married at the age of twenty-one; had one child five years ago, an easy parturition, and good recovery. Lactation was free. She nursed her child fourteen months, and her menses returned in twelve months after the birth of the child.

She had enjoyed excellent health until January, 1868, when, on rising in the morning, she became quite dizzy, and sick at the stomach, and so sore all over that she was scarcely able to move during the day. This condition was followed by great pain in the right side and in her bowels. This continued until about eight o'clock P.M., when the pain became so intolerable that Dr. White was summoned, and it was not until two o'clock next morning that she was relieved. The suffering continued for one week, after which she enjoyed pretty good health for about two years, when she was seized again with the same pain, and confined to bed for five weeks. After recovering from this attack a tumor as large as the fist, and hard, was discovered in the right side. This tumor always became sore on taking cold. It did not increase in size for one year, but in January, 1869, after an exposure, it began to grow, and increased rapidly afterwards. Her former weight was 132 pounds; now she is greatly emaciated. The lower extremities have been swollen since June; the left one swelled first.

She measures round the waist 34½ inches, round the umbilicus 51, from sternum to umbilicus 16, to pubes 28, and between the ilia 33½ inches.

The abdomen is very large, and covered with numerous dark-colored veins. It is pretty uniform in shape, although larger on the right side. The umbilicus is nearly obliterated. Fluctuation is very distinct. The tumor appears to consist mainly of one large cyst, with multilocular secondary cysts in its walls. The pelvis is free; the uterus is movable; the sound enters 2½ inches. Ovariotomy performed October 4, 1871. Drs. Burpee, Mears, W. Lemuel Atlee, Hoffman, Goodman, Packard, Millard, Forney, Goodell, and Sherwood, and Mr. Robinson, medical student, assisted.

The uterus was small and healthy; the intestines vascular; the omentum engorged with very large vessels; the parietal peritoneum very much thickened.

The tumor consisted of the right ovary. There was one large cyst, with secondary cysts in its walls; weight sixty pounds.

An excellent recovery followed. A letter dated April 2, 1872, says "she feels as well as ever."

TRANSLATIONS.

NEUMANN'S EXPERIMENTS UPON THE LYMPHATICS OF THE SKIN.*

BY LOUIS A. DUHRING, M.D.,
Of Philadelphia.

THE work of which the following is a brief abstract has quite recently appeared, and as the lymphatic system of the skin is a subject, comparatively speaking, unknown, the results of Neumann's investigations in this direction are here presented. Very little attention has heretofore been bestowed upon these vessels as they exist in the skin, and still less have they been studied in connection with the pathological changes of the corium.

It is to be hoped that the present series of experiments will be followed by others, with reference particularly to the condition of this system of vessels in certain diseases of the skin.

Dr. Neumann begins his observations with a review of the results obtained by previous investigators, referring in detail to the various methods and means employed for the injection of the tissue.

The plan adopted by Neumann for injecting the skin was a modification of the methods of Hyrtl and Teichmann. The epidermis and the corium having been well macerated in a mixture of alcohol, acetic acid, and water, a fine-pointed needle was thrust into the skin to the depth of a line or less. Into this little hole a delicate tube was inserted, and the injection then made by means of a small brass syringe. Two mixtures were used for the injection; one being composed of a carmine solution with glycerin, and the other carbonate of lead rubbed up with glycerin.

According to Neumann, the corium of the human integument is plentifully provided with lymphatics. They were demonstrated as existing in the papillæ, in the

* Zur Kenntniss der Lymphgefässe der Haut des Menschen und der Säugethiere. Von Dr. Isidor Neumann, Docent an der k. k. Universität in Wien. Mit 8 chromolithographirten Tafeln. W. Braumüller: Wien 1873.

upper and lower layers of the corium, in the subcutaneous and adipose tissues, and also in connection with the sebaceous and hair follicles, as well as the sweat-glands. Their presence in the papillæ was recognized in both physiological and pathological preparations. For purposes of physiological study the fingers and toes of new-born children were found to be particularly suitable, care being taken to inject also the blood-capillaries with some other colored injection-material. The papillæ are supplied by these vessels, either in the form of simple tubules, or, as is more usually the case, as loops which turn upon themselves about half-way up the length of the papillæ. These loops were beautifully exhibited in a series of papillæ. In the remaining portions of the corium they were distributed in such varied relations that it would be impossible to describe any definite arrangement. But it was especially noticeable that there existed a superficial and a deeper-seated stratum of vessels, which were bound in communication through a delicate network.

In addition to the fingers and toes of young children, where the lymphatics are most easily studied, Neumann mentions the scrotum, labia majora, perineum, prepuce and glans, and the skin of the internal malleolus, as being well adapted for examination. With the abundant available material at hand which the Vienna General Hospital liberally offers to any one pursuing scientific investigation, Neumann was enabled to examine the condition of the lymphatic system of the skin in a number of diseases, among which are mentioned examples of acute and chronic eczema, variola, Hunterian induration of the prepuce, cicatricial tissue after extirpation of sarcomas, and psoriasis palmaris and plantaris. In a typical case of eczema of the scrotum the papillæ were found very much enlarged and the lymphatic vessels likewise greatly increased in size. The lymphatics in the altered corium beneath were also strongly developed.

In five cases of acute eczema of the scrotum (three being spontaneous and the remaining two artificial eczemas) which Neumann had the opportunity of studying, the injections were made into the tissue, starting in the healthy skin just beyond the line of disease. Nothing, however, of interest was observed in these experiments, excepting that the sound skin was more easily injected than the diseased portion. It was found that in variola-pustules the upper stratum of the lymphatics was completely destroyed, while the deeper layer remained intact. In a case of Hunterian induration Neumann discovered that in the middle of the characteristic granulation-tissue of this disease, in which the normal corium had, in part, been destroyed, the lymph-vessels were present as thick, stout ramifications, stretching up into the enlarged papillæ and down as far as the sweat-glands.

In the experiments with the cicatricial tissue the injection was likewise made, starting from the adjacent sound tissue. The lymphatics here, few in number, were found to run more parallel, and were somewhat wider than normal.

The results of Neumann's experiments and observations may be summed up as follows:

1. The lymphatics of the skin present an enclosed tubular system, with independent walls, whose interior is lined with flat epithelium. These walls are nowhere interrupted by openings. There exists, therefore, no communication with the so-called juice-canals, or with other interspaces of the skin. Neither can spaces anywhere between the epithelium be noticed, not even in examples of disease where there exists an enlargement of these vessels.

2. The relation of the blood- and lymph-vessels is only constant to the extent that the former are always found much nearer the surface than the latter. The branches of the lymphatics, together with their meshes, are found spreading themselves in the deeper tissue in all directions. Nowhere, however, within a lymph-tubule could a second vessel be detected: so that there can be no ground for considering the question of invagination.

3. The lymphatics form two close and separate networks in the corium, the deeper being the more extensive of the two. Their walls are markedly capable of extension. The more superficial vessels are in general thinner; the deeper ones are thicker, and, like the first, are, to all appearances, without valves. Only among the subcutaneous vessels is it possible to demonstrate the valves plainly.

The larger lymphatics possess a number of branches with blind endings, which are of variable calibre. The lymph-vessels make their way into the papillæ of the skin, partly in the shape of single tubules, and also in the form of loops.

4. The appendages of the skin, as the hairs, hair-follicles, and sweat-glands, possess their own lymphatic capillaries situated about their periphery, but they do not enter into the follicles. The aggregations of fat are also surrounded by lymphatics. The vessels were found to be greatly developed in the subcutaneous tissue.

5. The number of lymph-vessels of the skin was found to vary according to locality. They occur in greatest numbers about the scrotum, labia majora, palms of the hands, and soles of the feet. In pathologically altered skin, an enlargement of the vessels was at times demonstrable.

In ulcerative processes the lymphatics are, in part, destroyed, though they may be regenerated. They occur only sparsely in cicatricial tissue. No vegetations were observed upon the walls of the vessels.

The brochure which we have been considering is accompanied by eight superb chromo-lithographic plates, the work of Dr. Heitzmann, of Vienna, well known for his success in producing correct drawings of microscopic pictures. The plates illustrate in a most satisfactory manner the conditions described by Dr. Neumann, and must remain a permanent contribution to the anatomy of the lymphatic system of the skin.

THE PATHOLOGY, ETIOLOGY, AND TREATMENT OF STUTTERING.

BY R. M. BERTOLET, M.D.

A BROCHURE upon the above subject, by Dr. R. Coën, has made its appearance (Wien, 1872). While the earlier writers attribute the affection to organic malformation of the vocal and speaking apparatus, others, on the contrary, viewed stuttering as a disturbance of the nervous system and of the central organ; latterly the disease has come to be regarded as the result of disturbed function of the respiratory organs. Coën is of the opinion that stuttering is to be regarded as a secondary manifestation and result of another pathological condition of the organism, namely, of anomalous size of the respirations. He was led to this view by the observation that the disturbance is most noticeable in the formation of those sounds which require a greater immediate action of the respiratory organs,—hence in the mute consonants; while the disturbance of speech is rarely or never manifested in uttering vowel sounds. In the formation of the mute sounds the vocal fissure is widely opened; the atmospheric pressure in the cavity of the mouth is then equal to that in the lungs, and the apparatus of the mouth must be sufficiently firmly approximated to give resist-

ance to this pressure. In the stutterer the atmospheric pressure in the lungs is diminished in consequence of defective innervation and consecutive disturbance of function; the apparatus of the mouth is, on the contrary, normally innervated, hence also disposed to offer a vigorous resistance to the irregular atmospheric pressure of the respiratory organs. If the air under such circumstances has to overcome a marked resistance, then this occurs only tediously, and the sound is pronounced at one time with difficulty, at another weak, indistinctly.

A disproportion between the diminished atmospheric pressure and the normal activity of the closing organs then ensues, and only after great effort is the air-pressure in the lungs increased, the firm closure opened, and the sound produced vigorously. In this manner is also explained the well-known fact that stutterers pronounce vocals quite well; that they can sing, declaim, speak loudly and slowly, without their defect being in the least manifested.

Stuttering differs materially from stammering: the latter consists in the inability to pronounce certain sounds and words completely and correctly, which can only arise as a result of malformation of the organs of articulation. It differs from stuttering in that it persists under all circumstances, excludes nervous and spastic conditions, and is evident also in singing and declaiming. According to Coën, the primary affection of stuttering must be sought in a central affection of the oblongata or in a spinal irritation, or in a combination of these two pathological conditions, whereby the activity of the respiratory organs is interfered with as a result of the disturbed innervation; *i.e.*, the atmospheric pressure in the lungs is diminished, and the action of the diaphragm becomes irregular.

That mental affections and increased spinal irritability are the causes which may produce stuttering is shown in its instantaneous appearance during the age of puberty upon injuries to the head and spine, in severe nervous affections, and especially from strong and rapidly acting irritants upon the nervous system. Here also are classed defective nutrition, abnormal formation of the thorax, debility of the respiratory muscles,—conditions which are induced by the primitive affection.

The *treatment* recommended is a methodically applied gymnastics of the lungs and electricity. In order to increase the force of the lungs, a forced inspiration and expiration, interrupted at short intervals, should be practised; in this manner the slow innervation is quickened and the tonicity of the lung raised. In order to remove the disproportion between the diminished atmospheric pressure and the normal articulation-muscles, the patient is ordered to make a deep inspiration before pronouncing each word of some selected sentence, so that the column of air is compelled to enter with force into the thoracic cavity; this occurs best when the patient inspires deeply with the teeth firmly pressed together. Then the word is spoken loudly and slowly at regular beaten intervals. After some practice an inspiration need only be made after every second or third word.

The indications for the electric treatment consist, first, in strengthening the inspiratory muscles by galvanization or faradization of the branches of the phrenic nerve and of the cervical plexus supplying the respiratory muscles. A second indication consists in combating the spastic condition by strong voltaic alternations. At the same time, a general water-cure and forcible friction (Swedish Heilgymnastic) of the respiratory muscles act against the dynamic causes which increase the affection. By the hydropathic cure it is claimed that a more cheerful psychical mood of the patient is induced, during which the depressing evil is forgotten and the hope of a recovery given room, an influence not to be despised in the treatment even of stuttering.

SUCCESSFUL EXTIRPATION OF KIDNEY.

By Prof. SIMON, of Heidelberg. Translated from *Schmidt's Jahrbücher*

BY DR. WILLIAM ASHBRIDGE.

THE patient who was the subject of this operation was a woman, 46 years of age, who eighteen months previously had been operated upon for the removal of an ovarian cyst, in the performance of which, owing to adhesions, it became necessary to remove a large part of the uterus. At the same time the left ureter was cut so that the surfaces of the wound were constantly inundated with the urine from the kidney of that side.

In spite of this, the patient recovered, but in a lamentable condition, suffering from a fistula in the walls of the abdomen, into one side of which the vagina and the canal of the cervix uteri opened, into the other side a fistula of the left ureter. The entire secretion of the left kidney found vent partly through the fistula in the abdominal wall and partly through the vagina. Professor Simon now attempted to restore the continence of urine. This he endeavored to effect by two methods before resorting to extirpation of the kidney. Twice he attempted a plastic operation, which failed in both instances, owing to the constant flow of urine, and twice he cauterized the fistula with argenti nitras. This latter method had to be given up, owing to the urgent symptoms which followed the retention caused by it. Upon the failure of these attempts nothing remained but the extirpation of the kidney.

The operation was commenced by a cut through the skin and superficial parts, about four inches in length. This cut was made on the outer side of the sacro-lumbalis muscle, in a perpendicular direction, beginning at the eleventh rib, and carried down to the middle of the space between the twelfth rib and the crest of the ilium. The next step was the exposure of the kidneys, the guides being the twelfth rib and the edge of the sacro-lumbalis muscle. The various fasciæ of the part and the intervening muscular tissue having been cut through, the operator at length arrived at the gland lying in its bed of fat. The next step—the separation of the gland from its surroundings—is described as the most difficult; the operator has to work under the rib, and must be careful to use only the finger or blunt instruments, to avoid the danger of a profuse hemorrhage from an injury to the parenchyma of the kidney. All the parts entering into the hylus must be ligated, either altogether in one ligature, or divided into two portions with two.

The course of the wound towards healing presented nothing remarkable; an attack of erysipelas and two attacks of diphtheritic exudation on the surface were the only untoward circumstances.

The ligatures did not come away until the beginning of the sixth month; but long previously the patient had left her bed, and was performing the duties of nurse in a military hospital in the early part of the late Franco-Prussian war, and two years after the operation she was still enjoying uninterrupted good health.

Accurate observations on the urine were made during recovery, and Professor Simon concludes that the extirpation of one kidney has no perceptible influence on the health of the patient. He also thinks that the remaining kidney can increase in size, remain of a normal size, or even be exceptionally small.

In experiments made upon dogs he found a vicarious growth of the remaining kidney beginning a very short time after the extirpation.

[In the first number of the *Philadelphia Medical Times* there is an allusion to the above case, containing a promise from Prof. Simon of a full report. Of this report the above is an abstract.—ED. P. M. T.]

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 26, 1873.

EDITORIAL.

THE SURVIVAL OF THE FITTEST.

A CURIOUS case of the application of the principle of natural selection under artificial circumstances is now progressing in our city. As every one knows, until the last year or two we have suffered in Philadelphia from a plague of "measuring-worms," which even Egypt in her palmiest days might have envied.

Some enterprising genius suggested the importation of English sparrows. A diet of worms resulted,—a diet which ended our plague. But the pest is coming upon us in a new form. The caterpillar of the moth *Orgyia leucostigma* opens his eyes a little later in the season than his friends the measuring-worms; consequently, for meals he in former times found the luxurious leaf-banquets in our public squares looking like the remains of an over-night club supper, and—didn't prosper.

Thanks to his hairy coat, the sparrows don't take a fancy to him; and, consequently, the measuring-worms being put out of the way, and the leaves allowed to grow, he is prospering and rapidly multiplying under the stimulus of food, good, abundant, and cheap. At present, very many trees in this city have again put on the familiar, woe-begone look of old, hiding their misery with the merest tatters and shreds of leaves.

"But the new-comer doesn't drop on you!" Doesn't he, though? If he does not drop he crawls, or gets on some way or other; and the man who has felt his long hairs tickling his neck, struck for a fly, and found in his hand a bare and *bursted* carcass, on his shirt-collar a stain, and down his back a bunch of tickling hairs, will vote the "survival of the fittest" in its latest form an unmitigated nuisance.

In order that our readers may avenge us on some of the mothers and fathers of these pests, we add a description of the perfected individuals as they will appear shortly:

Females wingless, or with merely two little wings like scales on each shoulder. Males with large ashen wings, crowned by wavy, darker bands on the upper pair, on which, moreover, is a small black spot near the tip, and a minute white crescent near the outer hind angle.

WE call attention to the following circular. The work that Dr. Butler is engaged in is, we think, of national importance and interest, and we cordially recommend immediate compliance with his request:

"Circulars calling for information for the Medical Register and Directory of the United States are being rapidly sent out, and this portion of the labor will soon be completed. It is earnestly desired that the responses be as prompt and as full as possible. *It is important to physicians, who have any education or standing, that they appear properly on this record,* as the work will be one of permanent value and will be constantly referred to. The forms containing the Directory of the first set of eleven States and Territories (Alabama to Georgia, alphabetically, inclusive) are now in the hands of the printer, and there are but a few days in which information can be inserted in those pages.

"Officers of public medical institutions of *all kinds*, hospitals, asylums, dispensaries, colleges, medical societies, etc., are particularly requested to furnish us with lists, catalogues, announcements, etc., in order to give brief histories of these institutions, and for use in perfecting the Register and Directory in all its parts.

"It is intended that the work shall be exhaustive, and as nearly *correct* as may be, and it will be issued as speedily as possible; but the labor is immense, and the work is delayed by the want of promptitude in receiving replies to circulars and letters.

"S. W. BUTLER, M.D.,
"115 S. Seventh Street, Philadelphia, Pa."

DR. MORITZ HEINRICH ROMBERG died of chronic cardiac disease on the 16th ult. He was born at Meiningen, and graduated in medicine at Berlin in 1817. Dr. Romberg's life appears to have been a laborious one, since he held the position of medical officer to the poor of Berlin from 1820

to 1845, and in 1830 and 1836 he was director of the cholera hospital in the same city. In 1838 he was elected extraordinary professor, and in 1845 ordinary professor, to the university at which he graduated. He is an instance of a physician successful in a special branch of medicine although doing a more or less general practice and writing upon other subjects. He was the author of a work on cholera, and of various contributions to the periodical press, but will be chiefly remembered on account of his treatise on the "Nervous Diseases of Man," which was first published, in three parts, in 1840, 1843, and 1846, and was in 1853 translated into English by Dr. Sieveking for the late Sydenham Society. At the date of its appearance it was undoubtedly the best book extant upon the subject upon which it treats.

AS the importance that India is assuming as a tea-producing country does not appear to be generally known, the following table of English imports will probably surprise some of our readers. It is taken from the *Food Journal:*

Year.	China and Japan.	India.
1864	120,284,000 lbs.	3,285,000 lbs.
1865	120,345,000 "	2,510,000 "
1866	120,213,000 "	5,133,000 "
1867	122,682,000 "	7,084,000 "
1868	118,480,000 "	8,132,000 "
1869	145,472,000 "	10,522,000 "
1870	141,500,000 "	13,149,000 "
1871	134,000,000 "	15,500,000 "
1872	147,000,000 "	17,164,000 "

DR. EDWARD WARREN, late professor of Surgery in the College of Physicians and Surgeons, Baltimore, Md., and most favorably known to the profession by reason of his testimony in the celebrated Wharton-Ketchum trial, has accepted the position of "Surgeon to the Staff of the Khedive of Egypt," with the rank of colonel, and the privilege of engaging in private practice in that country. His address is Cairo, Egypt, where he requests correspondence to be addressed. We cordially recommend Dr. Warren to the friendship and professional patronage of our countrymen who may be visiting Egypt.

IN consequence of the illness of Mr. Erichsen, of London, having assumed a somewhat chronic character, he has decided on withdrawing from all active professional work for some time, and taking that complete rest which is considered necessary for his recovery.

DR. H. C. WOOD, JR., desires us to state that he is no longer connected with the *Quarterly Journal of New Remedies*, published by William Wood & Co., of New York.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR:—The admirable suggestion of my colleague, Dr. William Pepper, in regard to injecting the veins of patients suffering from the collapse of cholera with a warm solution of bromide of potassium, promises so much in the treatment of this terrible disease that I feel anxious it should be tried on a large scale, under the most favorable circumstances. I therefore beg leave to propose to the profession, through your columns, a slight modification of the strength of the liquid Dr. Pepper recommends, by which it shall correspond to the three-quarter per cent. salt solution, so constantly and successfully employed by microscopists as an indifferent medium for the examination of the blood and likewise all the tissues it normally bathes. As the result of numerous experiments performed yesterday and this morning, I find that a fluid composed of fifty-five grains of bromide of potassium (or bromide of ammonium, which might be preferable in some cases of the greatest prostration), and a pint of water, has obviously under the microscope a much less marked effect upon both the red and white corpuscles of human blood than is produced by stronger solutions, such as that of grs. xv to f ℥j.

Any one who has studied the rapid changes which occur in the red disks and white globules by the osmosis of denser or rarer fluids with which they come in contact, as described in my papers upon the structure of those cellular elements, published in the Transactions of the American Medical Association, will appreciate the importance of accurately regulating the strength of the solutions employed.

Very respectfully,

JOS. G. RICHARDSON, M.D.

1620 CHESTNUT STREET, July 16, 1873.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JUNE 12, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. H. LENOX HODGE exhibited a *head and neck of the femur*, removed by excision, at the Children's Hospital, from a boy suffering from coxalgia. The operation was done this day, June 12.

The child is about eight years old. He has suffered from disease of the hip for three years. The head and neck of the femur are almost entirely absorbed. A

small nodule of cancellated structure is all that remains of the head. The neck is exceedingly shortened, and is diseased throughout. In this case there were bands of cartilage binding the femur to the sides of the acetabulum. These bands existed both on the exterior and in the interior of the joint.

Dr. WILLIAM PEPPER remarked upon the great difference in the mode and extent of the destruction of bone both in diseases resembling coxalgia and in others thoroughly unlike it, but suggested that in all instances there must be some solvent which removes the inorganic matter, and that when the bone has reached the condition of cartilage it undergoes softening. It was interesting to notice that there was here a tendency to the formation of new bone; and he desired to know of Dr. ASHHURST and Dr. HODGE whether they had frequently noticed a tendency to the development of osteophytes in this disease.

Dr. HODGE replied that, with regard to the formation of new bone, this was the only case of those in which he had excised the head of the femur that he had observed any tendency to it. Here there were bands of cartilage which in places were almost as hard as bone, and therefore difficult to cut with the knife. In no other case had he observed new bone or cartilage.

As regards the absorption of bone, this specimen exhibits what appears to be the usual course. First the articular cartilage disappears, then the compact substance, then the cancellated structure. In these cases there appears to be a far greater tendency to disease on the lower surface of the neck than on the upper. In extensive disease of the head of the femur, and of the lower surface of the neck, the upper surface of the neck is often healthy.

Dr. PEPPER said that the lower part of the neck of the femur was perhaps longer submerged in pus.

Dr. HODGE replied that generally upon excision of this joint none or very little purulent matter is found.

Dr. JOHN ASHHURST said that the seat of greatest destruction in hip disease varied with the particular part of the joint which was primarily implicated: thus, when the disease originated in the upper portion of the femur, it was easy to understand that the greatest destruction would be seen in the neck of the bone, and especially at its lower part, where the ligamentous structures were less dense than they were elsewhere; when the synovial membrane was first affected, the loss of substance would be chiefly observed on the convexity of the caput femoris; while in acetabular coxalgia, on the other hand, the pelvis would be most affected, and the thigh-bone only secondarily involved.

Natural efforts at repair were, Dr. Ashhurst said, less frequent in the hip than in the knee and elbow, where it was not uncommon to find anchylosis in one part of the joint coexisting with progressive caries in another. The process in these cases was properly called caries, or ulceration of bone, the term "interstitial absorption," as used by Paget, being more suitably reserved for that loss of substance, without suppuration, which was more common in the spine than in the articulations of the extremities. There was, no doubt, in either case a process of softening and conversion of bone into granulation-tissue, which might break down with suppuration or might undergo a retrograde change and lead to the formation of new bone.

Dr. R. M. BERTOLET said that the subject of the mode of absorption of the compact layers of bone-structure had been recently investigated by Wegner, of the Berlin Pathological Institute; that the important factor in the pathological process of bone-resorption seemed to be the myeloplaxes, or giant cells.

In a series of cases of rarefaction and absorption of the vitreous layer of the bones of the skull in consequence of diminution of the intra-cranial space from various causes, such as hydrocephalus, abscess, tumor, etc., upon examining microscopically the plastic layer which is always found covering the outer surface of the dura mater immediately beneath the points of absorption, Wegner unexpectedly discovered imbedded in a hyaline mass numerous multinuclear so-called giant cells freely anastomosing with one another. Lacunæ and depressions were found in the overlying bone-structure, corresponding in size and shape with the variously shaped myeloplaxes beneath; so that, no doubt, the resorption is brought about by the growth of successive layers of these cells.

The origin of these giant cells seems to be from a proliferation of the connective-tissue cells of the sheaths of the blood-vessels which exist in the surrounding vascular structure. Observations made upon other portions of the skeleton showed that in all cases of normal or pathological bone-absorption there is always present a proliferation of the cellular elements of the sheaths of the neighboring vessels, be they derived from the dura mater, periosteum, or medullary substance; in other words, giant cells are necessary for the resorption of bone.

REVIEWS AND BOOK NOTICES.

A DICTIONARY OF PHARMACEUTICAL SCIENCE. By H. V. SWERINGEN. Philadelphia, Lindsay & Blakiston, 1873.

We have very little to say about this book, either for or against it, simply because all our spare time has been spent in trying to imagine of what use it can be to any one—why or wherefore it was created. Time spent, too, in vain: we give up the conundrum. The work consists of brief definitions of terms, accounts of preparations, formulæ, etc. Possibly it may be of value to the apothecary's apprentice; but, so far as the medical profession is concerned, we doubt the judgment of the publishers. Yet who can tell? The springs of the pecuniary success of books seem to us, like sundry other things, past finding out.

CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL: including the Chemistry of the United States Pharmacopœia. A Manual on the General Principles of the Sciences and their Applications to Medicine and Pharmacy. By JOHN ATTFIELD, Ph.D., F.C.S., Professor of Practical Pharmacy to the Pharmaceutical Society of Great Britain, etc., etc., etc. Fifth Edition, Revised from the Fourth (English) Edition by the Author. Philadelphia, Henry C. Lea, 1873, pp. xv., 606.

The favorable opinion which we expressed on the appearance of the previous edition of this deservedly popular manual has been indorsed on all sides, and to such good purpose that this fifth edition has been called for, and has been specially prepared by the author for the American student, by whom we are sure it will be thoroughly appreciated. It contains some seventy pages more than its predecessor, and the chapter on the general principles of Chemical Philosophy has been rewritten and somewhat extended. In every way the work is worthy of its established reputation; and the appearance of this American edition does credit to the enterprise of its publisher.

THE FIRST ENGLISH OBSTETRICAL WRITER.—The first English midwife who appeared as an obstetrical writer was Mrs. Jane Sharp, of London, whose work was published in 1671, under the name of the "Midwives' Book,"—a duodecimo of 418 pages.—*N. Y. Med. Record.*

SELECTIONS.

RUPTURE OF THE JEJUNUM, FROM A FALL, IN A GIRL ELEVEN YEARS OF AGE.

BY E. G. HOLLAND, M.D.,

London.

H. P., described as a delicate, lively, and "fly-away" child, fell, at 4 P.M., and struck the umbilical region forcibly against the edge of the stairs. She uttered a sharp cry, got up, walked up-stairs alone, vomited the contents of the stomach untinged with blood, complained that she could not draw her breath, and lay down and slept for half an hour. On awaking, she got up, walked about, talked freely, and, though seeming faint, made no complaint of pain. At 9 P.M. she went to bed, without supper, and slept soundly nearly all night. At 8 A.M. she walked in her night-dress to an adjoining room, and, without complaint of pain, asked for water and ice. At 12, she walked alone down-stairs and lay down on some chairs, and, complaining a little of pain, had some hot flannels applied, but requested them to be removed on account of the "weight." At 4 P.M., for the first time, she asked for something to eat, and, after taking a few mouthfuls, vomited, fell back pale, and died without movement.

At the necropsy, thirty-six hours after death, the abdomen was found to be distended with flatus and fluid, and the umbilical region discolored by bruising. The peritoneal cavity was filled with a sero-flaky fluid, deeply tinged with bile. The peritoneum generally was minutely injected, and more or less universally covered with soft lymph. The jejunum was ruptured for nearly half of its circumference, twelve inches from the pylorus, and presented a bruised appearance on each side of the rupture. On cutting open the gut, it was found healthy, and its mucous membrane upraised by extravasated blood in the neighborhood of the rupture. There were no adhesions externally around the rupture, no thickening of the edges, and the latter dovetailed when laid side by side.

Comments.—The interesting features of this case are —first, the slight cause; secondly, the apparent absence of any severe suffering or shock, so that the friends did not consider her ill enough to require medical attendance until the fatal syncope set in, twenty-four hours after the injury; thirdly, the sudden termination, with vomiting, after taking food.—*British Medical Journal.*

GLEANINGS FROM OUR EXCHANGES.

Detection of the Biliary Acids in Normal Urine.—Prof. Vogel gives the following simple process for the detection of the biliary acids in normal urine (*Fres. Zeit.*, 1872, No. 4; from *Tagebl. der* 45. *Versamml. deutsch. Naturf. u. Aerzte in Leipzig*, No. 5, p. 75). Four or five ounces of the urine should be acidulated with a few drops of hydrochloric acid, and shaken for at least an hour with chloroform. The chloroform, which has become brown and turbid, can be separated from the urine by decantation, or with a pipette, and rendered clear by shaking with six or eight centimetres of absolute alcohol. The mixture is then to be filtered, and the chloroform separated from the alcohol by means of a pipette, and allowed to evaporate on a watch-glass. If this residue, which has a bitter taste, be treated with sugar and concentrated sulphuric acid, a violet color is produced, first around the grains of sugar; this color becomes changed to a brown in fifteen to thirty minutes (Pettenkofer's test).

In this manner Vogel found a small amount of the biliary acids in the urine of eight healthy individuals, and also in that of persons suffering from various diseases. In fact, no specimen examined failed to give the reaction for the biliary acids, when treated in this manner; and the color was more strongly marked in the urine of patients with disease of the liver (three cases of catarrhal icterus, one of carcinoma of the liver, and one of cirrhosis).

In order to be sure that this reaction was not caused by other substances, which may give a somewhat similar color with sugar and sulphuric acid (such as albumen, muscular fibre, various resins and oils, phenol, etc.), Dragendorff evaporated a litre of the urine of ten healthy individuals, varying in age from eight to fifty-five years, extracted the residue several times with alcohol, evaporated this, and dissolved again in water. This solution was precipitated with acetate of lead, dissolved in alcohol, and decomposed with sodic carbonate, carbonate of lead and glycocholate of sodium being the products of the decomposition, the latter remaining dissolved in the alcohol. From this solution the glycocholic acid was isolated, and its identity confirmed by Pettenkofer's test.

Not satisfied with this result, Dragendorff, by working with a large amount of urine (100 litres) in the above way, succeeded in obtaining a sufficient quantity of the acid to enable him to purify it by recrystallization and make an ultimate analysis of it, thereby proving beyond a doubt that the substance which thus reacts with Pettenkofer's test in normal urine is composed of the biliary acids, and that these do, under normal circumstances, find their way into the general circulation in small amounts, and are partially eliminated by the kidneys.—*Boston Medical and Surgical Journal.*

Separation of Carbolic Acid from Urine (E. Salkowski: *Fres. Zeitsch.*, No. 3, 1873; from *Archiv d. Physiol.*, Bd. v., p. 353).—The urine is made strongly acid with tartaric acid, and distilled until about one-half of the liquid has passed over. The distillate should then be shaken twice with ether, the ether decanted, and allowed to evaporate. The residue can then be treated with a little water, filtered if necessary, and Lex's test (see below) applied.

In 200 cubic centimetres of normal urine, no carbolic acid can be detected; but if 0.1 gramme be added (= 1 part in 2000) an intense blue coloration is produced, and this color can be perceived when the urine contains only one part in 4000.

Lex's test for carbolic acid is performed with ammoniac hydrate and calcic hypochlorite (chloride of lime). To the suspected fluid is added about one-fourth of its volume of ammonia-water, and then a few drops of a saturated solution of hypochlorite, and the mixture gently warmed to boiling. If much carbolic acid is present, a blue color appears immediately; but if only a minute amount, it does not appear until about fifteen minutes have elapsed. Too much calcic hypochlorite, or a too rapid application of heat, prevents the reaction. The fluid which has once turned blue may become colorless by standing; but the color can be restored by the addition of a few more drops of the hypochlorite. If the fluid is acidulated with sulphuric or hydrochloric acid, the blue changes to a red color.—*Boston Med. and Surg. Journal.*

The Best Catheter for Enlarged Prostate (by Prof. E. Andrews).—It seems not to be generally known, while men are inventing costly and complicated silver catheters for cases of enlarged prostate, that there is already in existence a very simple and inexpensive one, which is as near to absolute perfection as

human inventions usually get. I refer to Mercier's *sonde coudée*.

For cases of enlarged prostate, Mercier's *sonde coudée* is a splendid instrument. It slips into the bladder without resistance or pain, when every effort with the ordinary silver instrument only brings blood. The patient himself can use it with ease, safety, and comfort, and thus prevent much of the distress and misery which old men often suffer from retention of urine. It is not only in cases of enlarged prostate that this instrument is useful; it is superior to any other for nineteen-twentieths of the male patients by whom a catheter is required, and will, when it is better known, almost totally supplant the other forms now in use.

The *sonde coudée* is very simple. It consists of a black, flexible catheter, having two peculiarities:

1. Its walls are about twice or thrice thicker than the ordinary catheter, so that it possesses a mixed flexibility and firmness which enables it to conform easily to the curves of the urethra, and yet it requires no wire when inserted.

2. Half an inch from the tip it is bent forward at an obtuse angle. This curve is the peculiarity which enables it to slip past the overhanging central lobe of the prostate. Its extremity strikes the lobe obliquely, lifting it a little, while the flexibility of the instrument allows it to bend forward and evade the obstacle with the greatest ease.—*Chicago Medical Examiner.*

Local Use of Chloral Hydrate in Soft Ulcers and Ulcerated Buboes.—In an article published in the April number of the *Giornale Italiano delle Malattie Venerie*, Dr. De Paoli gives his experience of the local action of chloral hydrate in the above cases, such as was exhibited in the Clinique for Venereal and Skin Diseases of Bologna. Four cases are related, in which large ulcerated buboes were highly benefited in their last stages by the application of a solution of chloral hydrate (ten parts of chloral to thirty of water). The healing process was remarkably regulated and hastened by the application. The author thinks that in all sores with abundant suppuration and want of tone chloral is of the greatest use, and that its employment may be beneficially extended, as a slightly exciting and antiseptic agent, to suppurating wounds, and especially gunshot wounds. He states that Professor Gamberini has applied the same solution with marked results to the soft ulcers of prostitutes, especially during the later period of cicatrization, the virulent power and suppuration of the sores being considerably diminished, whilst auto-inoculation of the sores in other parts was not observed in the patients treated. He suggests that chloral hydrate may be a good substitute in certain cases for nitrate of silver and iodoform, and concludes, in summing up his paper, "that it diminishes the virulence of sores, has the advantage of not irritating the inguinal glands, and removes the offensive smell which proceeds from ulcers, especially those of the female genitals."—*London Lancet.*

A New Substitute for Quinine.—Among the specimens of drugs exhibited in the International Exhibition in Vienna is the *Echites scholaris*, a plant of the natural order *Apocyneæ*. It is especially abundant at Luzon, in the province of Batangar, in the Philippine Islands; and its bark has long been used by the natives, under the name of *dita*, as a remedy in all kinds of fever. Herr Gruppe, an apothecary in Manilla, has found in it an uncrystallizable, very hygroscopic, bitter substance, to which he has given the name of *ditaïn*. The principal Spanish physician in Manilla, Dr. Miguel Zina, has given it to numerous hospital patients under his care, and has found that ditaïn is not only a perfect substitute for quinine, but that its use is not followed by the disagreeable results which often attend the use of quinine. It is given in the same dose and in the same way as quinine. In many cases, also, its activity as a tonic was well marked. The ditaïn is prepared from the bark, in the same way as quinine from cinchona; 100 grammes of bark give 2 grammes of ditaïn, 0.85 gramme of sulphate of lime, and 10 grammes of a perfectly inactive extractive matter. A single tree yields a large quantity of bark without injuring its growth. It is calculated that the price of ditaïn in Europe would be about 160 francs per kilo (3*s.* 6*d.* to 7*s.* per ounce).—*The British Medical Journal*, June 7, 1873.

Amaurosis resulting from Poisoning with Morphia.—A case of this character is reported by Dr. W. Wagner, of Odessa, in *Schmidt's Jahrbücher* for 1873. The patient, a man 32 years of age, suffered from periodical attacks of vomiting, for the relief of which he had recourse to injections of morphia.

Having been attacked by his disease while upon a journey, during five days, he had prepared solutions containing 1.92 grammes of the acetate of morphia; but it is not probable that he used the whole amount. Dr. Wagner found the patient drowsy, with a small and slow pulse, both pupils contracted and fully immovable. The arteries of the retina were very much contracted; the veins normal. The light of a brightly-burning lamp was not perceived. In this state the patient remained for two days. Further observation was prevented by the removal of the patient by his wife without the permission of the doctor.

Chronic Pharyngitis, and its Cure by the Galvano-Cautery (E. Michel: *Deutsch. Zeitschrift für Chirurgie*, Band ii., 1872, 154–164).—The larger and smaller circumscribed hyperplasiæ of the mucous membrane which characterize granular pharyngitis are with difficulty healed by the ordinary methods resorted to (nitrate of silver). The author cauterizes quite superficially these granular enlargements with a galvano-cautery, and claims to have effected a cure in all cases with but three or four applications. The galvano-cautery thus operates more quickly, and at the same time is less painful, than the nitrate of silver and other caustics. For the lateral portions of the naso-pharyngeal space the laryngeal or rhinoscopic mirror must be employed.

Development of the Frontal Bone (*Reichert u. Du-Bois Reymond's Archives*, 1872, p. 649).—According to H. Jhering, the frontal bone, in addition to arising from two main centres, presents a number of accessory points of ossification. These are six in number, and are distributed as follows: two confined to the nasal spine; one placed on each side of the median line between the orbital and nasal portions of the bone; and one, which is described in detail, situated at the external lateral process. The last-mentioned is the most important of the accessory centres; since it occasionally remains distinct from the frontal up to the first or second year, and would appear to be homologous with the post-frontal bone of the skull of lower mamals.

Presence of Alcohol in the Human Urine.—After having shown that urine on putrefying produces alcohol, M. Béchamp has sought to discover alcohol in the urine of persons who had previously been subjected to a *régime* of abstinence from wine and alcoholic drinks. In the urine collected in these conditions, and in which fermentation had been prevented by the addition of a little creasote, M. Béchamp has found enough alcohol to be able to set it on fire. In one of the experiments there was enough alcohol in two litres of urine to be determined by the alcoholometer. The author believes that the liver produces alcohol physiologically.—*London Lancet; from Gazette Médicale de Bordeaux.*

ATROPIA SUBCUTANEOUSLY IN CHOLERA.—Dr. Hodgen mentioned (Proceedings St. Louis Medical Society, June 7, 1873) a plan of treatment pursued by him in a few cases at the close of the epidemic of 1866, with results considered sufficiently encouraging to merit further trial. In the *stage of collapse*, the doctor injected subcutaneously from a sixtieth to a thirtieth of a grain of sulphate of atropia, and injected freely into the bowels warm water with a little salt in it; reaction and convalescence followed in over half the cases without fever. The doctor also referred to the importance of promoting the action of the kidneys as early as possible, by diuretics and warm poultice or fomentation over the kidneys, not to eliminate the cholera-poison, but to obviate uræmia.—*St. Louis Medical Journal*, July, 1873.

ACTION OF THE INTERCOSTAL MUSCLES.—Dr. Thomas Dwight (*Boston Medical and Surgical Journal*, 1873) has reviewed the literature of this much-discussed subject, besides investigating the function of the intercostal muscles in the dog. He concludes that the theories of Hutchinson and Hamburger are to be modified. The intercostals have little influence on ordinary respiration; they are for the most part passive structures, though both internal and external muscles at times raise the ribs, and by sudden action may be made to perform the part of accessory expiratory muscles. Both sets in the lower part of the chest may tend to draw the ribs downward. Slight causes may modify the action of any part of them.

POISONING BY ALUM.—A fatal case of poisoning by the ordinary potassium alum is reported in full by Dr. Hiequet (*Ann. d'Hygiène*, January, 1873), with the chemical analysis of the tissues, and remarks upon the toxicology of alum. It was caused by the accidental ingestion of about an ounce instead of Epsom salts. The symptoms and lesions produced were those of a corrosive acid poison, there being found destruction of the epithelium in the mouth, throat, œsophagus, and stomach, two gangrenous patches in the small intestine, and also extensive peritonitis.—*Boston Medical and Surgical Journal.*

DEATH FROM HEAT-STROKE IN A VAPOR-BATH.—An inquest was held at Stratford, Essex, a few days ago, on the body of a man who died while taking a vapor-bath in the public bath-rooms of the locality. The temperature of the bath at the time of the occurrence was not, according to the evidence of the proprietor of the rooms, above 110°; but Drs. Whitehouse and Kennedy, who had examined the body soon after death, expressed their belief that it could not have been less than 200°. The jury returned a verdict of "Death from coma, accelerated by the use of an over-heated bath."—*London Lancet.*

MISCELLANY.

A DOCTOR'S STORY.

BY W. M. CARLETON.

I.

Deacon Rogers he came to me;
"Wife's a-goin' to die," said he.

"Doctors great, an' doctors small,
Haven't improved her any at all.

Physic and blister, powders and pills,
And nothing sure but the doctor's bills!

Twenty old women with remedies new
Bother my wife the whole day through;

Sweet as honey, or bitter as gall,—
Poor old woman, she takes 'em all:

Sour or sweet, whatever they choose,
Poor old woman, she daren't refuse.

So she pleases whoe'er may call,
An' death is suited the best of all.

Physic and blister, powder an' pill,—
Bound to conquer, and sure to kill!"

II.

Mrs. Rogers lay in her bed,
Bandaged and blistered from foot to head.

Bandaged and blistered from head to toe,
Mrs. Rogers was very low.

Bottle and saucer, spoon and cup,
On the table stood bravely up;

Physic of high and low degree,
Calomel, catnip, boneset tea:

Everything a body could bear,
Excepting light and water and air.

III.

I opened the blinds; the day was bright,
And God gave Mrs. Rogers some light.

I opened the window; the day was fair,
And God gave Mrs. Rogers some air.

Bottles and blisters, powders and pills,
Catnip, boneset, syrups and squills,

Drugs and medicines, high and low,
I threw them as far as I could throw.

"What are you doing?" my patient cried;
"Frightening Death," I coolly replied.

"You are crazy!" a visitor said;
I flung a bottle at her head.

IV.

Deacon Rogers he came to me;
"Wife is a-comin' around," said he.

"I re'lly think she will worry through:
She scolds me just as she used to do.

All the people have poohed and slurred—
All the neighbors have had their word;

'Twas better to perish, some of 'em say,
Than be cured in such an irregular way."

V.

"Your wife," said I, "had God's good care,
And his remedies,—light and water and air.

All of the doctors, beyond a doubt,
Couldn't have cured Mrs. Rogers without."

VI.

The Deacon smiled, and bowed his head;
"Then your bill is nothing," he said.

"God's be the glory, as you say!
God bless you, Doctor! good-day! good-day!"

VII.

If ever I doctor that woman again,
I'll give her medicine made by men.

—*Maine Farmer.*

THE SHAH OF PERSIA AND THE CONVENTION OF GENEVA.—We are authorized to state that the visit of his Majesty the Shah of Persia to this country has resulted in an act which will be highly agreeable to lovers

of humanity. Through the interpreter, the Shah expressed the warm interest which he felt in this subject, and his desire to give diplomatic adhesion to the convention of Geneva, for neutralizing the sick and wounded in war, and the persons and materials provided for their succor. The convention has already been signed by all European monarchs, including the Sultan of Turkey, who gave his adhesion in 1865. The protocol of the convention was left open in 1864 at Bern. The adhesion of the Shah will, therefore, be addressed to the High Federal Council of Switzerland. The Shah is already familiar with the emblem and its present merciful significance among European troops in time of war. The red cross was flying, at the review at Windsor, over the ambulance in the rear, which was drawn up facing the saluting-point. In Austria, in Switzerland, and in Sweden, all medical officers and the hospital staff corps bear the *brassard* on parade and during movements of troops in peace, in order to popularize the emblem and to make its meaning familiar. The Shah is the first purely Asiatic monarch who has given his adhesion to the convention and to the merciful principles which it establishes. M. Henry Dunant, who has devoted the best years of his life and has sacrificed all his private interests to the development of the humanitarian idea with which he was inspired by the sight of the horrors of Solferino, must be earnestly congratulated at seeing the fertile idea, which has taken firm root throughout Europe and has borne noble fruit there, now planted in the soil of Asia. *It is strange that, of all civilized powers, the United States of America has alone withheld its assent from the convention.—British Medical Journal.*

Vehicle for Chloral Hydrate.—J. G. Plumer, in *London Phar. Jour. and Trans.*, recommends, as the best vehicle for administering chloral hydrate, the syrupus flor. aurantii of the British Pharmacopœia. We have ourselves found nothing to answer better than essence of peppermint for disguising the peculiarly acrid and nauseous taste of the drug.—*Detroit Review of Medicine.*

"Smart.—An American paper says, 'Massachusetts is noted for two things: intelligence and patent medicines.' We presume the intelligence is displayed in selling, not in taking, the physic."—*Fun.*

The Regents of Michigan University have decided not to appoint the homœopathic professors, as ordered by the Legislature.—*The Clinic.*

Cholera of a malignant type has appeared at Cawnpore, and smallpox rages at Lucknow.—*London Lancet.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 15, 1873, TO JULY 21, 1873, INCLUSIVE.

Woodhull, A. A., Assistant-Surgeon.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 143, A. G. O., July 15, 1873.

Smart, Charles, Assistant-Surgeon.—When relieved by Assistant-Surgeon Meacham, to report in person to the Commanding General, Department of the Platte, for assignment to duty. S. O. 143, c. s., A. G. O.

Miller, George McC., Assistant-Surgeon.—Assigned to duty at Camp Grant, Arizona Territory. S. O. 51, Department of Arizona, June 20, 1873.

Lippincott, H., Assistant-Surgeon. — When relieved by Assistant-Surgeon King, to comply with orders received from War Department. S. O. 125, Department of the South, July 12, 1873.

Meacham, Frank, Assistant-Surgeon. — Assigned to duty at Fort Monroe, Virginia. S. O. 143, c. s., A. G. O.

De Witt, C., Assistant-Surgeon.—Assigned to duty at the Presidio of San Francisco. S. O. 86, Department of California, July 11, 1873.

Yeomans, A. A., Assistant-Surgeon.—Assigned to duty at Fort Garland, Colorado Territory. S. O. 108, Department of the Missouri, July 17, 1873.

King, William H., Assistant-Surgeon.—Assigned to duty at Atlanta, Georgia. S. O. 125, c. s., Department of the South.

Weekly Return of Deaths and Interments in Philadelphia for the Week ending Saturday, July 19, 1873.

ORIGINAL COMMUNICATIONS.

AN INVESTIGATION INTO THE ACTION OF CONVULSANTS.

BY DR. H. C. WOOD, JR.,

Clinical Lecturer on Diseases of the Nervous System to the University of Pennsylvania.

THERE are certain drugs and poisons acting upon the nerve-centres, which give rise to a lessening of reflex activity and to paralysis. There are others which increase the reflex activity and produce convulsions. Those substances which lessen the functional activity of the cord are known as *spinal depressants*, and those which enhance it are known as *spinal stimulants*. So far the matter is plain ; but there are other drugs, universally considered to be *spinal depressants*, which produce both convulsions and lessening of the reflex activity,—which, in other words, apparently diminish, and at the same time increase, the spinal functions. This seems at first rather odd, and, indeed, the apparent paradox has led some students into believing that such drugs as aconite and veratrum viride really excite the spinal centres.

It has occurred to me that the convulsions seen in these cases may have their origin in the brain, and not in the spinal cord. If this be so, it is evident that section of the spinal cord should prevent the occurrence of any convulsive movements below the point of division. If the convulsions are of spinal origin, it is equally evident that the previous division of the cord would have no influence in interrupting the spasms.

The following experiments were instituted to test this matter. In the first, *strychnia* was used, so as to afford a point of comparison. The drugs were all administered hypodermically.

Experiment 1.—A full-grown cat. The cord was cut in the upper dorsal region.

TIME.	DOSE.	REMARKS.
10 A.M.	gr. ss.	
10.4 "		Slight convulsive twitchings in hind legs.
10.6 "		Clonic spasms, with rigidity, in hind legs. Front legs relaxed.
10.10 "	gr. ss.	Constant convulsions in posterior portion of body. Anterior part quiet.
10.14 "		Facial convulsions, with foaming at mouth.
10.16 "		Front legs convulsed for the first time.
10.20 "		General convulsions.

It is a noteworthy fact in this experiment that the portion of the spine below the point of section was affected by the convulsant much earlier than the part still in connection with the brain. This certainly affords strong confirmation of Setschenow's theory of an inhibitory reflex centre at the base of the brain.

The experiment also accords with the universally received fact that convulsions of strychnia are of spinal origin.

The next substance studied was *aconite*.

Experiment 2.—A powerful male cat. At 4.30 I cut the cord in the upper dorsal region. The poison used was tincture of aconite root.

TIME.	DOSE.	REMARKS.
5.15	15 minims.	
5.31	20 "	
5.45	25 "	
5.48		The cat has just had a violent convulsion, which was confined exclusively to the head and neck.
5.55	35 "	
6.5		The cat has had a number of very violent convulsions, all of them exclusively confined to the portion of the body above the point of section.

Experiment 3.—A cat was killed by the aconite, as in the preceding experiment, and had a number of convulsions exclusively confined to the part of the body above the section of the cord.

The next poison employed was *prussic acid*, U.S.P.

Experiment 4.—A cat with the spine cut in the middle of the dorsum.

TIME.	DOSE.	REMARKS.
0 minutes.	f3ij.	
4 "		Convulsive movements of head and legs.
15 "	f3j.	There have been incessant convulsive movements of the head and fore legs, the hind legs remaining perfectly quiet.
20 "		Perfect unconsciousness, muscular relaxation, and anæsthesia of the cornea.
27 "		Dead.—During the last five minutes of life the hind legs were drawn slowly up upon the body, and very slowly extended, several times ; the same thing happened, but not consentaneously, in the front legs.

Experiment 5.—A small cat with the dorsal spine cut. A f3ss of officinal prussic acid was injected hypodermically. In less than a minute a violent, prolonged convulsion came on, confined to the anterior extremities, and apparently accompanied with unconsciousness. After this had gone off, there was the same peculiar stretching of the hind legs, as well as of the front legs, seen in the previous experiment. In another moment the animal was dead.

The next substance used was *veratrum viride*. Unfortunately, I have been unable to procure any of the alkaloids, and was consequently forced to use the fluid extract.

Experiment 6.—A powerful male cat, with the cord cut in the upper dorsal region.

TIME.	DOSE.	REMARKS.
	20 minims.	
20 minutes.		Violent convulsions, confined to that part of the body above the section.
80 minutes.		There have been a great number of violent convulsions, which have been confined to the upper portion of the body, affecting exclusively the front legs, neck, and head.

Commercial *veratria* was next employed.

Experiment 7.—A large female cat; the cord cut in the upper dorsal region.

TIME.	DOSE.	REMARKS.
4.21 4.35 4.50	3 grains. 1 grain.	Has had numerous severe convulsions. The part below the point of section has been affected as much as any other.

Experiment 8.—A young kitten; the cord cut in the middle dorsal region; veratria injected.

TIME.	DOSE.	REMARKS.
3 minutes. 7 "		Has had a general convulsion. Hind legs affected. Dead.—On opening the body, the heart was found beating vigorously.

Experiment 9.—A pigeon; cord cut in the upper dorsal region; veratria injected half an hour afterwards.

TIME.	DOSE.	REMARKS.
2 minutes.		Violent general convulsions, some of which appeared to be produced by external irritation, affecting all parts of the body, the legs as well as the wings.

Experiment 10.—A large cat; cord cut in the middle dorsal region.

TIME.	DOSE.	REMARKS.
25 minutes.	3 grains.	The cat has had numerous violent convulsions, in which the parts below the section were affected earlier than those above, and throughout they were more strongly convulsed than the upper part of the body.

These experiments prove that the convulsions caused by prussic acid, aconite, and veratrum viride are not of spinal origin, whilst those produced by veratria do arise from the spinal centres. I confess that I was very much surprised by the latter result. The alkaloid was the commercial article, probably of German origin; several samples from different stores were employed indifferently, all acting alike.

As prussic acid, aconite, and veratrum viride are such powerful depressors of the circulation, it very naturally occurred to me that perhaps the convulsions induced by them, being cerebral, are due to the want of blood at the base of the cerebrum. In investigating the truth of this supposition, evidently the first matter to be settled is whether there is any relation between the activity of the circulation and the occurrence of the convulsion. On referring to my article in the April number of the *American Journal of the Medical Sciences*, for the year 1870, upon viridia and veratroidia, I find that in Experiment 16 (viridia) before a convulsion occurred the arterial pressure had fallen from 140 to 70 mm. In Experiment 17 (viridia) the arterial pressure fell from 125 to 77 without the occurrence of a convulsion. In Experiment 21 (viridia) the arterial pressure fell from 154 to 80, yet no distinct convulsion occurred, only convulsive tremblings. In Experiment 22 (viridia) the arterial pressure fell to 70 before the convulsion occurred: unfortunately, the normal pressure was not noted. It is evident that in these experiments the convulsions from viridia-poisoning did not occur until the arterial pressure had been reduced to one-half its normal amount. Veratroidia was found to act less energetically upon the circulation, and the convulsions also were fewer and less severe than those induced by viridia. In Experiment 19 (veratroidia), however, the original arterial pressure was 140; it fell to 80, but rose again to 117, at which point it was when convulsions came on. As far as these results go, they seem to indicate a connection between the state of the circulation and the occurrence of convulsions.

The following experiments were made to see whether in aconite-poisoning any similar relation exists between the circulation and the convulsions. Morson's pure aconitia, obtained directly from the manufacturer, was used.

Experiment 11.—A moderate-sized dog.

TIME.	DOSE.	CARDIOMETER.	REMARKS.
0 m.	½ grain in periton'l cavity.	120 to 130 when quiet.	
3 "		115 to 120, dog being very quiet.	Respiration evidently affected, deep, labored.
5 "			Dog vomiting.
10 "		70 to 115, the mercury following the slow labored action of respiration; individual heart beat scarcely affected.	Arterial blood as dark as venous.
13 "			Dog died quietly, without the slightest trace of convulsions; apparently completely paralyzed.

Experiment 12.—A moderate-sized pup.

TIME.	DOSE.	ART. PRESSURE.	REMARKS.
1 m.	¼ grain in periton'l cavity.	Mostly about 175.	Dog struggling.
5 "			
9 "		125 to 160; mostly about 135.	Dog is exceedingly quiet, not moving a muscle; respiration affected.
15 "		60 to 90, but nearly all the time below 75.	Pupils slightly dilated; left decidedly larger than the right. Respirations 16. Pulse 76.
20 "			Pupils much dilated; unequal. Dog struggling, apparently semi-convulsively, or else the movements are efforts at vomiting; previously animal had lain absolutely quiet. Respirations very irregular.
25 "			Dead. Some distant, decided efforts at respiration were made after the pulse had stopped in the femoral. Just before death there were one or two stretching movements of muscles; otherwise, the dog died quietly. There was no distinct vomiting.

Autopsy.—Heart soft, enormously dilated, and congested. Left side full of bright arterial blood. The auricles (especially their appendages) making some efforts at contraction. When cut, the auricles moved more actively; slight fibrillary movements were also produced in the right ventricle by cutting it and afterwards pricking it. The left was immovable by mechanical excitement.

In neither of these experiments were convulsions induced. This was somewhat surprising, but of course does not disprove that aconitia convulsions when they do occur are due to disordered brain-circulation.

The following experiments were performed to determine whether the aconitia I had would produce convulsions in other animals than dogs.

Experiment 13.—A full-grown rabbit.

TIME.	DOSE.	REMARKS.
	⅙ grain.	
2 minutes.		Rabbit very restless; running around in a very peculiar manner; jumping suddenly forward and upward. Respiration labored.
5 "		Rabbit very weak, and profoundly affected, with labored breathing. There is great loss of muscular power, but he has just had a violent general convulsion.
6 "		Dead.

Autopsy.—Immediate. The heart was found soft, dilated, full of dark blood; when seized with the hand, pulsating very feebly. It was uncertain whether the pulsation was excited by hand or was spontaneous. Blood everywhere very dark.

Experiment 14.—An adult rabbit.

TIME.	DOSE.	REMARKS.
	¼ grain.	
½ minute.		Rabbit jumping as in last experiment.
7 minutes.		Rabbit unable to stand, lying on his side, giving repeated sudden, apparently involuntary, kicks with his legs.
8 "		A feeble general convulsion.
9 "		Dead.

Autopsy.—Immediate. The left ventricle beating very feebly, with no propulsive force; the right dilated, soft, full of black blood. Blood everywhere dark.

These experiments show that upon rabbits the aconitia does induce convulsions. It has occurred to me that the reason motor disturbance is not brought about in dogs is that the paralytic action of the alkaloid upon them is proportionately so intense as to prevent the development of the convulsions which would otherwise occur from the disturbance of the circulation at the base of the brain. If this be so, evidently any artificial means of increasing the disturbance of the brain-circulation ought to aid in the production of convulsions, or, conversely, if by artificially increasing the disturbance of the circulation in the base of the brain, naturally produced by aconitia, we can cause convulsions in the dog, it becomes exceedingly probable that the motor disturbance produced by the drug is really due to deranged brain-circulation.

The following experiments were performed to test this question:

Experiment 15.—July 9, 1873.—A stout terrier, in which one of the carotids had been tied four days before the present experiment.

4.7 P.M.—Injected $\frac{1}{60}$ grain of pure aconitia.

4.17 P.M.—Injected $\frac{1}{20}$ grain? (The amount may be incorrect.)

4.35 P.M.—Attempting to vomit.

4.37 P.M.—Convulsive movements, with violent efforts at vomiting.

4.50 P.M.—The dog has been lying upon his side ever since last note, with occasional most violent and noisy efforts at vomiting, and constant convulsive movements, forcing his body into every conceivable position.

4.55 P.M.—Died quietly, simply stretching out the feet stiffly in the agony.

Experiment 16.—A young impure pointer bitch. July 12, 1873, in the morning I tied the left carotid, and at 4 P.M. put a tight ligature round the right; no apparent result.

4.9 P.M.—Grain $\frac{1}{20}$.

4.42 P.M.—Since last note the dog has had about $\frac{1}{6}$ of a grain.

4.58 P.M.—Dog is barking hoarsely. There are very active movements, in regard to which it is impossible to say how far they are voluntary, how far convulsive. Pupils somewhat dilated.

4.55 P.M.—Dog lying on his side, kicking convulsively with the hind legs.

5.3 P.M.—A general muscular effort, apparently not voluntary, but convulsive.

5.14 P.M.—The dog has had a number of very violent spells of vomiting and retching. Some of these would commence with a general convulsive movement, which would pass off with a violent effort at vomiting.

5.15 P.M.—Dog leaped into the air, apparently involuntarily.

5.22 P.M.—There have been a number of very decided convulsive spells ending in violent retching. Between these the dog lies on his side; in them he turns about, throwing his body clear over.

5.25 P.M.—There have been several decided convulsions affecting all the muscles of the body, and not ending in vomiting.

5.35 P.M.—A long, general, tonic convulsion, followed by a few gasps and death.

These experiments seem to show that both vomiting and convulsions are induced in the dog by aconitia when the blood-paths are artificially narrowed, and when, consequently, the disturbance of the brain-circulation naturally produced by the drug is artificially increased.

In conclusion, as the convulsions induced by the class of drugs now under consideration are of brain-origin, as they only occur after the circulation is profoundly affected, as they are increased by artificial narrowing of the cerebral blood-paths, and as disturbance of the circulation of the base of the brain is known to cause convulsions, it seems to me highly probable, if not actually proven, that the convulsions induced by these substances are secondary and dependent upon deranged cerebral circulation.

Since this paper has gone to press, it has occurred to me that perhaps there is a difference in the convulsive tendency of animals: by this I mean that

one animal is much more readily and violently convulsed by disturbances of the cerebral circulation than is another. Further, it has seemed possible that the dog is not convulsed by aconitia so actively as is the rabbit, because his convulsive tendency is less. It is very evident that if this were to prove correct, the argument that aconitia does convulse by acting on the cerebral circulation would be greatly strengthened. It would be like "proving a sum" in the arithmetic lesson of the juveniles. I therefore opened the left carotid of a dog whose right carotid had been tied some hours previously, and, when he failed to bleed to death from this, the femorals. The convulsions were decided, but by no means severe; they did not cause any marked alterations in the position of the body, and occurred only during the last moments of life. In a rabbit, however, which was bled to death from its carotids, the most violent convulsions occurred, the body being thrown about in all directions, the animal pitching forward on its head and turning somersaults, etc.

POPLITEAL ANEURISM.

CASE TREATED AT THE PRESBYTERIAN HOSPITAL.

BY OSCAR H. ALLIS, M.D.,

One of the Surgeons.

THOMAS M., æt. 50; colored; temperate; has always been a healthy man. On the 11th of last May (1873), while engaged in carrying *three-bushel* sacs of potatoes up out of the cellar, he experienced a sharp pain in his right foot, which he supposed to be rheumatic. On the following day he noticed a swelling in the right popliteal region, and found the knee-joint somewhat stiffened. The swelling increased rapidly, and in less than a week he was obliged to desist from labor.

Admitted into Presbyterian Hospital, May 24, 1873. *Present Appearances.*—Patient is tall, with large frame, muscular, well nourished, having the appearance of bodily vigor and soundness. There is in the right popliteal space a pulsating tumor. This tumor is hard, not compressible, and does not diminish in size when the femoral is compressed. It extends about three inches above the joint, and lies in the middle of the popliteal space. Pulsations synchronous with those of the femoral are felt distinctly on the sides of the knee-joint and over the body of the tumor, and disappear on compressing the artery above. There is no thrill communicated to the hand, though a *bruit* is distinctly heard over the body of the tumor. The knee is much swollen, and the leg and foot are œdematous. He complains of pricking sensations in the foot. There are no signs of degeneration in the coats of the vessels in the arterial system. The sounds of the heart are clear, and, except a little hurried, normal.

I will be excused if I do not enter into the treatment of the case with what might seem a tedious minuteness, and instead will give the more striking features in the order in which they occurred.

On Thursday, May 26, I flexed the limb and confined it with a bandage. This was continued for two days and nights, and, finding that the knee and leg were becoming more swollen, was discontinued.

One week later, a Lister's tourniquet was applied over the femoral near the apex of Scarpa's triangle, as there were many enlarged glands higher up in the inguinal region. The tourniquet at first gave much pain, and was loosened after two hours; but tolerance was soon established, and the pain borne with remarkable fortitude. After the tourniquet had been worn for two days, I deemed it advisable to substitute digital compression. This, strange to say, was very irksome to the patient, who would at intervals of two hours request the reapplication of the instrument, during which times he would obtain sleep, and at no other. At the expiration of thirty hours, finding it difficult to obtain sufficient help, I discontinued digital compression, to the entire satisfaction of the patient, but continued the instrument until the following day. Compression, either manual or instrumental, had now been kept up for four days; and, as the region compressed was becoming tender, I deemed it best to desist from further interference for the present, and in the mean time to give him iron stimulants and a generous diet. The foregoing treatment had perceptibly diminished the pulsations in the tumor, which had now disappeared on the side of the knee and were most distinctly felt directly over the popliteal space.

I will here mention a most unfortunate complication in the case. The bandage applied to the foot and leg —carefully applied and affording the patient comfort— was, by a fold in the popliteal space, the occasion of a transverse fissure. This fissure was only through the skin, or at most through the superficial fascia, and not deemed at the time of any importance. It was touched with the stick of nitrate of silver, and dressed with a cerate. The patient never complained of any pain in it, and, though it seemed to increase a little in size, it still gave no external evidence of the undermining going on in the structures of the popliteal space, until Thursday, the 12th, eight days after cessation from compression, when a sudden hemorrhage took place, which proved to have come from the still pulsating aneurismal sac.

A consultation with my colleagues at the hospital favored a second attempt in compressing the artery, and in thirteen hours all pulsation in the sac had ceased. While compression was going on, the foot and limb became very cold, and warm bottles were placed about them.

On visiting my patient the following day, I was a little surprised to see symptoms of gangrene extending well up the leg. Free longitudinal incisions were made through the skin and deep fascia, and stimulants, with iron, quinine, and opium, freely administered. The symptoms at this time were of a low typhoid character, except his pulse, which ranged from 108 to 120 and was quite firm and even. The condition of the man remained unchanged from this time until his death, which took place eight days after the first appearance of the gangrene.

Post-mortem Examination.—1. Whole popliteal space sloughed away. No remnant of the sac to be found.

2. The clot extended from the sac about an inch into the artery, where it was adherent.

3. The places compressed by the tourniquet appeared as if bruised.

4. The tissues about the femoral artery had not been so compressed about it as to have rendered ligation more difficult.

5. No atheroma in the large vessels.

6. No signs of disease in internal organs.

In regard to the case whose history has just been related, two queries present themselves for consideration:

1. Was the gangrene the result of compression?

2. Ought amputation to have been resorted to immediately on the supervention of gangrene?

It is claimed for compression, and especially digi-

tal compression, that its results are never prejudicial to life or limb, and that whenever it fails and ligation follows, it may almost be regarded as commendable preparatory treatment, since by it the collateral circulation has in a measure become established, and the danger of gangrene thereby greatly diminished; and this the statistics of cases fully confirm. I have found but one case of gangrene resulting from compression, and but one of fatal erysipelas; but neither of these can justly be regarded as prejudicial to this *mode* of treatment of aneurism.

In my own case I believe the gangrene was due to the condition of the popliteal space.

Let me here refer to the history of the slough in the ham. On the 4th of June, sixteen days previous to his death, a mere fissure was noticed traversing the lower part of the popliteal region, scarcely deeper than the skin, and caused, as I have already mentioned, by the bandage in a fold of skin in the popliteal region. Under ordinary circumstances this fissure would not have been caused, or, if caused, would have healed in a few days; but in a swollen œdematous limb, elevated in temperature and imperfectly supplied with blood, it soon assumed alarming proportions, and in eight days involved the aneurismal sac. To this condition of the popliteal region, and to this alone, must be attributed the disastrous results of compression.

As to the second consideration, Ought amputation to have been resorted to *immediately* on the supervention of gangrene? Certainly it would seem to have been the only remaining chance of saving life. There appears to be no conflict of authorities upon this subject. Those that are not altogether silent upon it state that amputation should be resorted to as soon as symptoms of gangrene present themselves.

I deferred amputation because my patient had every symptom accompanying a low typhoid state of the system, with the single favorable symptom—a pulse of one hundred and twenty. I am convinced now that every moment lost when gangrene is imminent renders the case more hopeless; and were I to be placed in like circumstances again I would amputate, if I felt my patient had sufficient vitality to bear the shock.

TUMOR OF THE BRAIN.

BY T. D. DAVIS, M.D.,

Dayton, Ohio.

Read before the Montgomery County (Ohio) Medical Society.

TUMORS of the brain mostly give rise to such marked symptoms that "he who runs may read;" but sometimes they resemble other brain-diseases so closely that accurate diagnosticians may be excused for disagreeing. I cannot assent to the opinion of some when they assert "that, with few exceptions, the diagnosis of tumor of the brain is but a guess, and the determination of its locality is impossible." Certainly there is no pathognomonic symptom; for there is no one symptom arising from tumors that does not occur in other brain-troubles; but there are certain groups of symptoms which, with a careful history of the case, will, I think, enable us to decide.

Mr. L., aged 39; married for seventeen years. Used neither alcoholic drinks nor tobacco; pattern-maker; family generally healthy, with no history of any brain-lesion. For some years past he could not do any kind of work which jarred him or caused him to stoop, such as splitting wood or digging in the garden, as it would make him sick at the stomach and his head dizzy.

In March, 1872, he had a carbuncle on the back of his neck, and was never so well afterwards. About this time he commenced to lose his memory for names. In May he began to complain of a violent pain in his head, and to be sick at his stomach occasionally in the mornings. He was very restless at night, and moaned and groaned a great deal, and on being awakened would say his head pained him. He would come home from his work in the evenings and lie down on the floor and sleep there until late at night, and then declare he could never go to work again. On being wakened in the morning, he would complain of great weariness. About this time he noticed his sight failing him while reading, but was able to see to work. Had a very good appetite. His bowels were obstinately constipated, although he never complained of pain in them. He was able to continue at work until the middle of June. At this time all of his symptoms had increased. He was constantly sick in the mornings at his stomach. Marked aphasia was present. Appetite became very poor. There appeared to be impairment of all his special senses. He could not distinguish the different articles of food. His hearing became indistinct. The latter part of this month he had a slight inflammation of the bowels, possibly caused by the medicines administered.

In July all the symptoms were growing worse. When he would take a walk he would have to stop and vomit, and once stopped three times in a single short walk. On one occasion he had a spasm; his limbs gave way, and he had to be helped home. From this time his gait was more and more unsteady. He had full power to move both his legs, but after walking a few moments he would get weak in his knees, drag his toes, stumble over small obstacles, and complain of feeling dizzy. In August he had several more spasms, which came on him while lying down, and he became perfectly unconscious. His legs would wrap round each other when he attempted to walk, but he could move them around in the bed as he pleased. His hands also became unsteady. He could hold anything for a few moments, and then would let it drop. There was no paralysis, but a loss of power to keep the muscles contracted for any length of time (paresis).

In September he became very drowsy and restless, and still suffered constantly with the violent pain in his head. Profuse sweats commenced, the perspiration rolling down his face. His left eye became affected with squint, and he lost the power of opening fully the lids of the same eye. The pupils were about the normal size, and *evenly dilated*. The temperature of both sides of the body was the same, although not tested with a thermometer. There was still no paralysis of any of his limbs. The weather seemed to have a marked effect on him, as he was very much brighter on rainy days and in fine dry weather suffered most intensely. From this time until his death, on the 18th of November, his symptoms remained much the same. The convergent strabismus and ptosis were augmented. There was no more paralysis developed, but paresis was increased. For two or three days he would be

comfortable, with the exception of the excruciating pain in his head; then for twenty-four hours he would become very nervous and restless, and then he would pass into a comatose condition for twenty or thirty hours, and on wakening would be very much prostrated. His strength continued to fail. He could still hear and see some. There was complete aphasia, he being unable to recall the name of the most familiar article, with this wonderful exception, that he could *lead in prayer with a clear voice and well-pronounced words.* This was the more remarkable as he did not pray by rote, but framed *new* petitions each time. During the whole course of the disease there was no febrile attack. He died calmly and peacefully, after remaining comatose for forty-eight hours.

The question arises, Of what disease did our patient die? To say nothing of the intestinal trouble for which it was once mistaken, but which mistake could not possibly have lasted more than a few days, there are but a few others from which to separate it. All acute brain-diseases are at once excluded. It might be confounded with meningeal hemorrhage, chronic meningitis, abscess, or encephalitis, softening of the brain, or tumor. From the first of these it is readily distinguished by its not coming on suddenly: this disease can rarely be mistaken for any other when a full history of the case can be obtained. The history also excludes chronic meningitis, as it almost invariably begins with an acute attack, advances more rapidly, gives rise to febrile symptoms having exacerbations, the pain not being constant nor of the same character, paralysis more usually present, the special senses rarely affected alone, the intellect more disturbed, its duration and course much different. As to abscess or encephalitis, although any one of the symptoms narrated may be present, yet it has not the history of this case. The absence of a cause is a strong argument against abscess, as it is mostly the result of an injury or some acute inflammation of the brain or its membranes, or is due to necrosed and diseased bone. True, it may be dependent on the inflammation set up by the pressure of a tumor; but then we would have had the acute symptoms. It never advances so insidiously, nor lasts so long. It almost invariably produces many more prominent brain symptoms and disturbances. We know that large abscesses sometimes remain hidden and are not suspected until post-mortem examinations reveal them; but they never have the exact history of this case.

We have, then, but to determine between softening and tumor of the brain. In well-marked cases of each of these diseases there would be no trouble in discriminating them; but this case has so many symptoms in common with both that the very greatest care must be observed in deciding. Softening can, like the preceding diseases, mostly be traced to a cause, but some cases come on so slowly as not to be suspected until the symptoms have become grave. Still, even then we may trace it to its source,—caries of some of the cranial bones, injury to the head, apoplexy, hemorrhage or embolism, inflammation, some heart trouble, atheroma of the arteries, etc. The pain in softening is always dull, and when attended with exacerbations, the pain then resembling that of tumor, there is more or less febrile action with it. In this case the pain was very violent and continuous. Softening, unless the result of an inflammation set up by a tumor, rarely becomes so chronic. The perfect example of paresis, the aphasia, and the almost total absence of paralysis, all point to softening as the cause. But the absence of increased pain on the moving of the head, the steady, severe pain continuing so long without other marked brain-symptoms, the convulsions and their character, the marked paralysis of the third nerve, the impairment of the special senses, the absence of any febrile symptoms, the exacerbations in fine weather, the total want of any cause, the long duration, the slow and gradual development and extension of the local symptoms, the patient's inability to tell when the disease began, the retention of his intellectual powers, the marasmus, the constipation of the bowels, the failing of the health by asthenia, the absence of any general or well-marked paralysis just before death, and the calm and peaceful death while comatose, all point strongly and conclusively to a tumor in the brain. The proof of tumor announced by Ziemssen was not tried.

If the diagnosis of a tumor is difficult, the diagnosis of its location is still harder. Occasionally tumors may be so well marked that the crudest anatomical knowledge of the brain will enable us to locate them; but in this case no such accurate diagnosis could be made. The small amount of intellectual derangement and paralysis would show us that it was central and did not encroach much on any of the great nerve-centres. The absence of hemiplegia would indicate that it was not in either side of the cerebrum, or in the crus cerebri, or on one side of the pons, and not likely on one side of the cerebellum. The absence of pain in the back of the head would be quite strong proof that it was not in the posterior cranial fossa. The want of an ophthalmoscopic examination prevents us from knowing whether the impairment of sight was owing to atrophy of the optic nerve the result of pressure or of venous congestion; but it was most probably the latter, as his powers of vision varied.

As to the kind of tumor, we would from the symptoms be as much at a loss to decide as to its location. There was no history of carcinoma in his family or himself. There was no tuberculous history; and his age would be against such a conclusion. No atheroma of his arteries to point to aneurism; no parasites in other organs; and no suspicion whatever of syphilis. There is one point which I have never seen noticed, but which may be of value as a symptom of cystic tumors. When the air was rare, he was affected more and the pain was much more severe; caused, perhaps, by the tumor expanding when the air was dense from moisture, as just before or during a rainstorm he was much easier. This being the opposite to the course of most pains makes it noticeable.

On post-mortem examination, which I made thirty-six hours after death, a cystic tumor, about the size and shape of a pullet's egg, was found in the left ventricle. It had been ruptured, perhaps in the removal of the brain; but the thickness of its

wall, with the careful handling of the brain, would incline me to believe it was done ante mortem, more especially as it was afterwards inflated by the blow-pipe and bore a very considerable pressure without again rupturing. Its contents appeared to be simple serum. Its wall was about one-sixteenth of an inch in thickness, and was dimly translucent, almost opaque, with a large deposit of lymph of a brown color all over its inner surface. It was attached to the septum lucidum by about three-fourths of an inch of its wall. The thalamus opticus was nearly entirely atrophied, and the corpus striatum had a large depression for its accommodation. The brain-tissue around bore no signs of inflammation or softening. The brain itself was normal throughout. That part of the brain usually regarded as the seat of verbal memory was entirely unimplicated, so far as could be discovered.

One of the most remarkable features of this interesting case was the character of the aphasia. It was purely amnesic, as there was no paralysis whatever of the organs of speech. He could repeat distinctly any word after you pronounced it, but he would miscall the commonest article. Wanting his hat, he would ask for his boots, and be surprised when they were brought to him; and it was sometimes impossible for him to tell his wishes without resorting to signs. But even in *his worst stages he could frame and pronounce accurately a long prayer*, and his last words were uttered in prayer for his children. If, as we have been taught, aphasia is dependent on a change in the brain-structure or on pressure, how was this possible? If the pressure or absorption of the corpus striatum was sufficient to prevent a communication with the organs of speech, how could he pray? And yet he would arise from a well-worded prayer and be utterly unable to name his children.

TRANSLATIONS.

ANIMAL STARCH.

BY WM. ASHBRIDGE, M.D.

TWO years ago, C. Dareste observed in the yolks of hens' eggs microscopic nuclei, which manifested physical and chemical properties resembling those of starch, and to which, for this reason, he gave the name of animal starch.

These assertions met with much opposition; and this can readily be understood when the difficulty with which the nuclei are recognized is taken into account, for in the yolk of the egg they are mingled with albuminous, colored oils, and that fat containing phosphorus to which the names lecithin and protagin have been given. These substances often mask the characteristic reaction with iodine and interfere with the conduct of these nuclei when viewed by polarized light. The observer is compelled to separate them on the slide of the microscope,—a proceeding requiring much time and patience, and in which a satisfactory success is quite exceptional. At length, however, Dareste discovered a manipulation by which he demonstrated the existence of starch in the yellow of the egg. This is, to place a few drops of the contents of the sac of the yolk upon a slide; these are to be taken from the egg just at that period of incubation at which the sac has fully separated itself from the contents. The yellow globules have at that time undergone a species of digestion, the first effect of which is to separate the various elements of which they consist.

By the aid of polarized light a large number of nuclei are seen, which possess the optical properties of starch, properties which have not been observed in any other non-crystallized substances. The average diameter of these bodies does not exceed .025 millimetre.

With iodine they do not always give a blue, as they would if procured from an egg that has not been partially hatched, but sometimes assume a reddish hue. This is due to a commencing absorption: it was observed also in vegetable starch by Nägeli. The globules of the yolk then contain starch, but during the latter part of incubation it is absorbed and vanishes. This agrees with another fact observed a long time ago by Lehmann, namely, the presence of glucose and its increase during incubation; for it is manifest that this glucose results from the metamorphosis of the starch. By the aid of a very delicate apparatus for polarized light, Dareste succeeded in observing the characteristics of starch even in very fine nuclei; he found also that the starch is not present in constant quantity, but rather that during the development of the egg in the ovary, and that of the embryo in the egg, several periods of generation of the starch-granules can be established.

The earliest of these periods is while the egg is yet in the ovary. In this position it undergoes a series of changes which as yet are very imperfectly understood, but there comes a time in the life of the ovum when there can be observed upon the inner side of the outer membrane a collection of minute starch nuclei arranged in isolated groups. When and how this first manifestation occurs is unknown; whether they are totally absorbed before the formation of the yellow globules in the yolk, or whether they are the beginning of the same nuclei which appear in the yolk, is equally a point for further investigation. Then follows a second period of generation,—that to which allusion was first made: it only remains to add that, as a rule, the starch nuclei in this period are larger, both than those occurring in the earliest stage, and than those described later. In the third period the process goes on in the cells of the mucous membrane of the blastoderm. Finally, a fourth generation of starch takes place in the liver; the nuclei here produced are the smallest that have yet been seen, and can be recognized only with the highest powers of the microscope, but their optical properties leave no doubt of their true nature. They produce, beyond doubt, the "glycogenic matter" observed by Bernard.

There are thus, then, probably four periods of the generation of starch in the egg, from its first appearance in the ovary till the young creep forth. As yet there has been no explanation given of this successive appearance and disappearance of starch in the hen's egg. Perhaps some idea in regard to it may be formed by noting the isomerism between starch and glucose, the readiness of the metamorphosis of the former into the latter, and the probability of the regeneration of the starch at the cost of the glucose. The wandering of starch into the various parts of plants is explained in this way. According to the observation of Sachs, starch is created only in chlorophyll by the influence of sunshine, and always passes into the parts not containing chlorophyll in the form of glucose. This theory, according to Dareste, can be applied to animal physiology as well, for he thinks starch gets into the animal economy in the form of glucose, and has its source, either directly or indirectly, in the vegetable parts of the diet. He had suspected the existence of starch in the fecundating secretions of animals; and this he confirmed by experiments chiefly upon birds.

TREATMENT OF PNEUMONIA BY CARDIAC MEDICAMENTS.

By Dr. Max Legrand. Translated from *L'Union Médicale* for May 15, 1873,

BY JEAN PAUL BONSIEUR, M.D.

THE following is an epitome of the lectures of Professor G. Sée, delivered at the Charité:

Treatment by Digitalis.—This drug is the cardiac medicament *par excellence*, as many experimenters have proved. M. Marcy, professor to the College of France, held that digitalis increased the intravascular pressure and by this means slowed the action of the heart and also increased its strength. Professor Sée, while admitting the increase of the arterial tension, asserted that this was not the cause of the decreased action of the heart, that being influenced through the pneumogastric. La Pommeraye, MM. Tardieu and Roussin, show that section of the vagus nerve interferes with the action of the poison. That is true; but they do not entirely suppress its action. MM. Cl. Bernard and Vulpian demonstrate that, after section of the vagus, digitalis will still act on the heart. They are all right, relatively. Digitalis acts not only on the pneumogastric, but also on the intrinsic ganglion of the heart itself, and probably on the muscular tissue. We always observe in the physiological state, after the exhibition of digitalis, a decided slowing of the pulse, a considerable diminution in the amount of urea (from 20 to 30 per cent.), with a falling of the temperature from half a degree (Centigrade) to one, one and a half, or even two degrees: consequently, digitalis is one of the most energetic antipyretic agents in the materia medica.

Digitalis acts slowly; and, unfortunately, pneumonia always needs energetic interference, it being necessary to wait from twenty-four to forty-eight hours for the action of this drug, which often throws us on to the critical days. What is more, this being a cumulative drug, we must exercise great care in its administration.

Now, we can give five grammes of bromide of potash per diem to a patient; at the end of eight hours its action is over, the bromide being so rapidly eliminated. And so to determine the phenomena of intoxication in an animal, if we inject, to-day, one milligramme of nicotine under the skin, it is necessary to use twice the amount to-morrow to produce the same effect, the system so soon becomes accustomed to it.

Digitalis comports itself otherwise; with a decoction of 0.50 centigramme of the leaves we obtain a slowing of the pulse after from twenty-four to forty-eight hours, and the dose being renewed, the diminished action is continued. It is important to be alive to its peculiarity, not to be impatient and force the dose for quicker action, or the gravest consequences may follow.

Administered in pneumonia, the temperature is lowered, with a decrease in the number of arterial pulsations; the fever is diminished on the first or second day after exhibition, similar to that which occurs naturally on the seventh day; which effect we have the right to claim for the drug.

The lowering of temperature is not always coincident with the decreased pulse-rate, the temperature falling first; oxidation being diminished, dangerous congestions of the internal organs do not follow. The fall is not always to the normal figure (37°.5 Centigrade), but descends to 40°, 39°, or 38°.5, where it stays.

En résumé, digitalis does not abridge the duration of this disease, in spite of the assertions of Traube and Hirtz; the fever is not suppressed, but only diminished. We use this drug not to extinguish the malady, but to attenuate it.

Digitalis is useful in alcoholic pneumonia, and is very much used for this form of disease in America. The delirium appears not only in old drunkards, but in the habitual drinkers of wine; alcoholic delirium is a bad expression; a more correct one would be delirium from suppression of alcohol. The onset of the pneumonia is always sudden; the temperature rises in five or six hours to 39° or 40° Centigrade. Wine is given to bring down the delirium, with a full dose of a narcotic, as we give in all violent affections of the nervous system. We also employ digitalis in large doses, without carrying it so far as the American physicians, who do not fear to prescribe fifteen to twenty or even thirty grammes of the tincture in the twenty-four hours. None of their patients die; showing that large doses are well supported in delirium. This is what they call a therapeutic tolerance.

TREATMENT OF ACUTE ARTICULAR RHEUMATISM BY CHLOR-HYDRATE OF TRIMETHYLAMINE.

By Dr. L. Martineau. Translated from the *Gazette Médicale*

BY JEAN PAUL BONSIEUR, M.D.

SINCE the introduction of this drug into notice by Dr. Dujardin Beaumetz, I have had occasion to witness its excellent effects.

Case.—X., compositor, æt. 34, attacked March 7, after chill and fever, with articular pains. Never suffered from rheumatism; no hereditary taint. On the 8th I diagnosed acute articular rheumatism. All the joints of the superior and inferior extremities were swollen and extremely painful; the patient being incapable of the slightest movement. The pulse was full, strong, and frequent,—89 per minute; perspiration very abundant.

The following prescription was ordered:

℞ Aq., parts (by weight) 100,
Aq. menth. pip., parts (by weight) 40,
Syr. aurant. cort., parts (by weight) 30,
Trimethylaminæ chlorhydrat., part (by weight) ½.
M. et Sig. Exhib. coch. mag. om. bis hor.

March 9.—Insomnia, abundant perspiration, urine increased; pulse full, strong, 69; articular pain less intense, disappeared from some joints; swelling and redness still persistent. The patient takes the medicine with pleasure, the taste being masked by the peppermint-water, though the odor still persists.

March 10.—Slept four hours during the night; slight moisture on the skin; pulse full, large, 60 to the minute; tongue clean; appetite good; the articular pain has entirely disappeared, together with the redness and tumefaction. The patient is now able to move his limbs without pain, and with the greatest facility. The medicine is well received by the system; no gastric trouble. Continue prescription every four hours.

March 11.—The amelioration continues; the patient keeps his bed, in order not to compromise his cure; pulse large, 51 to the minute; skin slightly moist; no cerebral or cardiac involvement; appetite good; urine abundant; sleep perfect. Continue the prescription through the following day. Discharged.

Genesis of Uric Acid.—Dr. Powlinoff, of Moscow, considers that by finding a quantity of uric acid in the blood of a pigeon, whose renal vessels he tied, he has proved its existence as such in the blood, and that it is only separated by the kidney, and not formed there, as Zalesky, Meissner, and Chrzonszczewsky consider.—*Centralblatt f. d. Med. Wissensch.*, April 5, 1873.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 2, 1873.

EDITORIAL.

THE APPOINTMENT OF RESIDENT PHYSICIANS IN OUR HOSPITALS.

WE have long thought that the method of appointing resident physicians or internes followed in the various hospitals of Philadelphia is the worst possible for securing the best results to the patients of the individual hospitals, to medical science in general, or to the especial medical interests of our city. Like kissing, the appointments to medical residentship in the hospitals with us go by favor, —universally so, we believe, except in the Philadelphia Hospital, where an examination is held, whose results, although they do not absolutely decide in all cases, influence very greatly, the elections.

Then, again, there is no grading of the internes, —the graduate of yesterday having just the same rights, privileges, and responsibilities as the interne just completing his period of service.

This seems to us totally wrong. In defence of the system of appointing visiting surgeons and physicians and professors in medical colleges without *concours*, it may be pleaded that the candidates by the time they have arrived at a sufficient age have so far achieved their respective reputations as to make a judicious choice possible without any immediate test of fitness. Not so with the fresh graduate, however. Who knows whether the youth ascending the platform on Commencement-day is, or is not, to be a second Galen? Possibly his private tutor; probably no one else. Some test of fitness other than having sprung from the loins of a father prominent in some church, or a friend of bank-directors and other mighty men of valor among the money kings, or of having been nursed in the lap of a queen of society or of a mother in Israel, is needed; and, with all its faults, a rigid but fair competitive examination without doubt affords the best known test.

Again, this method of preference is so injurious to the interests of medical teaching in this city that, were we not well accustomed to such traits of character, we should wonder at the supineness of the medical faculties in not using their influence to have the mode of choice altered and the places thrown open to competitive examination. Men are drawn on in this world by hopes. Brilliant chances drag the multitude captive, though it be well known the chance is only one in a thousand for each individual.

One of the sources of success of Bellevue and other New York colleges is, undoubtedly, the well-known fact that the appointments to Bellevue, and, we think, also to Charity Hospitals, are open to any one by competitive examination. Certainly in this city we could offer one chance to every five, or at most ten, of the graduates who would desire the position of resident physician, if the plan of competitive examination were only introduced. But no! owing to the sheer inertia of old practice, owing to the want of enterprise or effort of the authorities of our medical schools, the vicious system protracts its life, and is introduced into every new hospital as it opens. It is useless for the faculties of our schools to plead want of power in this matter. The reform is certainly needed on other grounds than those of the interests of the medical schools; and if the united faculties of our colleges have not enough energy, eloquence, and influence to achieve this simple change, we suggest that it would be well for them to let others, who have these needed qualities, occupy their positions.

Further, we do most earnestly object to placing the highest authority and responsibility at once in the hands of the interne. The thing is too preposterous to need comment:—life and death hanging upon the word of a man who is almost of necessity unacquainted with more than the first rudiments of practical medicine, and mayhap does not even know the theory of his art! The visiting physician is not, and cannot be, always present. In distant hospitals he does not even see the patients once a day. In the Philadelphia Hospital he is not required to visit more than three times a week. It is absurd, then, to claim that he can do more than direct the general plan of treatment. In many emergencies the sufferer

might be dead, if not buried, before the official visit was due. No wonder that we so often witness serious results from the mistakes of resident physicians,—mistakes which even the most capable and judicious must make when thrust into responsible positions with only the training of the lecture-room and class-room.

The system employed at Bellevue Hospital, New York, obviates these very serious difficulties. There the appointee is at first *provisional externe*, his chief duty being to act as substitute in case any officer of the next grade should be absent or sick or should be himself acting as substitute in a superior rank. After six months' duty, the provisional externe becomes *junior assistant externe*, whose duty it is to act as a general assistant, to copy histories into record-books, cup, leech, etc., and, when needed, to act as substitute to his superior. Both of the externes live outside of the hospital, but are required to be present during the day, and take their dinners in the institution.

After a six months' service, the junior assistant becomes a *senior assistant interne*, resides in the hospital, takes histories, and attends to patients as the *house physician*, the highest grade of interne, directs. All of these grades, it should be stated, are responsible to, and under the control of, the latter functionary. The subject of substitution is not left, as in our hospitals, to the whims of residents or their chiefs, but is all directed by one of the visiting staff, chairman of a standing committee, who by virtue of his sole authority is able to reduce the absence of the internes to something like a just system.

No doubt it will be said, All this looks well on paper, but it has been tried in the Philadelphia Hospital and failed,—failed because the junior and the senior residents quarrelled in the most bitter manner. In truth, however, the plan works well in practice in Bellevue Hospital. How can any plan be made to work in a headless hospital? It failed in the Philadelphia Hospital because there was no one to control the young men,—no person in the institution having authority over them. Anarchy would of course, sooner or later, result in such a case, through the want of courtesy and consideration, or the downright tyranny, of some of the constantly changing chief internes.

In Bellevue they manage better than this. A warden, of sufficient ability and firmness to command respect, is the executive officer of the hospital, and absolutely governs the resident staff. As the result, everything works smoothly, the residents do their duty, and official quarrelling is impossible.

THE WHARTON TRIALS AGAIN.

WE have received from Dr. Philip C. Williams, of Baltimore, a pamphlet (an extract from the June number of the *Richmond and Louisville Medical Journal*, 1873) purporting to be "A Reply to Dr. H. C. Wood's Review of the Medical Testimony in the Trial of Mrs. E. G. Wharton for the Alleged Attempt to poison Mr. Van Ness," with an autographic letter requesting a notice of it in the *Philadelphia Medical Times*. As the profession has already been surfeited *usque ad nauseam* with the "Reviews" and "Counter-reviews" that have appeared in connection with these two Wharton trials, we do not propose to tax the patience of our readers nor to occupy our pages with any extended comments.

The pamphlet before us, like a preceding one by the same author, written as an "Answer" to Dr. Reese's Review of the first Wharton Trial, displays in a high degree the earnestness, we may say the *enthusiasm*, of the writer to maintain his own ground despite the odds against him. Notwithstanding the verdict of acquittal in the first trial, and notwithstanding the abandonment of the case by the State in the second trial, our champion refuses to "give up." Like the "man convinced against his will," he "is of the same opinion still." Like Goldsmith's school-master, "e'en though vanquished" he will "argue still."

Dr. Williams, moreover, does not hesitate to question the correctness of Professor Taylor's (of London) information in regard to the first Wharton trial; although this gentleman in his criticisms upon it, in the new edition of his "Principles and Practice of Medical Jurisprudence," distinctly refers his readers for his authority to the "report of the trial *in the Baltimore Gazette*," and *afterwards* to the "*Am. Jour. Med. Sciences*, April, 1872" (containing Dr. Reese's Review). It seems to grieve Dr. Williams that so high an authority as Dr. Taylor should have made such a "mistake" as to differ from himself and colleagues in his conclusions. Well, it is a pity that such eminent savants will differ; particularly as the unfortunate result must be, according to Dr. Williams, that "it exhibits great carelessness in Dr. Taylor," and that "it weakens our confidence in his work as *authority* in medical jurisprudence." Alas! poor Taylor! A name that *was* so bright!

Another wrecked reputation is that of "Wharton and Stillé," for we read in the recent edition, "This disease [*i.e.*, cerebro-spinal meningitis] has been confounded with poisoning by tartar emetic in the

trial of Mrs. Wharton," etc. We do not see what is left us,—unless, indeed, Dr. Williams will write us a book that shall be an authority.

In conclusion, we think that Dr. Williams has not strengthened his cause by charging his professional opponents with *intentional lying*, which is about all his pamphlet amounts to. It may be that their reputation for veracity is as good as his own, or even a "trifle better."

WE are always glad to note the recognition in a far country of work done in America. We see that the India *Medical Gazette*—the leading medical journal of the land where sunstroke most prevails—editorially adopts the name of "thermic fever" for sunstroke, as well as the pathology and theory of the disease advocated in the recent monograph published in this city, giving due credit to whom credit is due.

We also notice that a writer in the London *Lancet* of July 5 confirms the value of earth as a topical dressing, provided a suitable form of it be used with judgment. Earth containing much organic matter he finds to do harm; also sand with sharp particles. The best he found to be common earth, consisting of disintegrated ferruginous sandstone,—*i.e.*, silica,—from the vicinity of Simon's Bay.

Another writer in the same issue of the *Lancet* praises highly the instrument invented by Professor Gouley, of New York, for the relief of stricture.

IT is even more pleasant to see some ponderous German or corky Frenchman fall upon his nose through neglecting American medical literature than to witness the recognition abroad of results achieved. It gratifies at once the sense for the comic, the love of a mild revenge, and the national pride. A correspondent of *The Clinic* clearly sketches as follows the mistake of our friend Dr. A. Hermann, of Pesth, in regard to the early diagnosis of cholera:

"'*I have succeeded in discovering a symptom which will decide with certainty whether a given case be cholera or not*,' etc. And further along he says, 'The discovery of the author consists *in the detection of albumen cylinders and epithelium in the urine during the time of the precursory diarrhœa*.'

"In both extracts the italics are Dr. Hermann's own. On page 188 of 'Notes on the Origin, Nature, Prevention, and Treatment of Asiatic Cholera' (second edition), by John C. Peters, M.D., D. Van Nostrand, Publisher, 192 Broadway, N.Y., 1867, the gentle reader will find the following:

"'Albumen, epithelium, and tube-casts appear early in the urine, and increase rapidly in quantity. These appearances are manifest in the very inception of the diarrhœal stage, and are of great importance both in a diagnostic and therapeutical point of view.'"

JUDGMENT has proved adverse to the lady students at Edinburgh on their appeal to the Court of Session. The tribunal was a very competent one, and the arguments *pro* and *con* were reviewed with clearness and impartiality. Three of the judges hold, or have held, high office in the universities of Scotland; while seven others have taken an active part in academical administration.

CORRESPONDENCE.

MIDDLETOWN, CONN., July 21, 187 .

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR:—Below you will find the history of a singular case which came under my care about three months ago; and, as I think it to be a rare one, for I have not read of any other like it, I thought it would be of some interest to the profession.

Jerome P., æt. 20, American, and with no predisposition to syphilis, came into my office on the 19th of March, 1873. The patient had been suffering from a running sore situated on the sacral region, between the bodies of the first and second sacral vertebræ, the effects from what he called "a big boil," and which broke from a fall he received at the time, while skating. He had been to other physicians seeking for relief, but could get none. When I first saw the case, I thought at the time some of the sacral bones might be necrosed, or the periosteum might be affected; but upon my examining the case more closely, by means of a probe, I found that I could not feel any roughness, and could see the point of my probe come through the tissues, so that so far it was nothing but a blind fistula as deep as a common-sized probe. As I was a little puzzled, and desirous of getting a view of the thing, I made up my mind to make an operation, which anyhow had to be done in order to cure the patient. So I explained to him the nature of the case, and at once obtained his consent. I operated on him in the following way:

I placed a grooved director in the wound, and made a little opening at the bottom of the fistula for the director to pass through, and then, with a curved, sharp-pointed bistoury, laid open the fistula from below upwards, and, to my surprise, I found on the point of my knife quite a mass of hair, which at once revealed to me the real cause of the trouble, and, to my mind, this acted like a seton, thus keeping up a continual irritation and producing a most horrible and offensive discharge, which was not very pleasant to the olfactory nerves, and a source of trouble and nuisance to the patient.

How that hair got in there, is no easy matter for any one to know, unless he was acquainted with the case; and here let me remark that the fistula had three small openings, close to each other (big enough for the probe to go through), and communicating together into one, about half an inch from the point of entrance. The patient was a very hairy man, and that accounts, I think, for the hairs getting into these openings, may-be one by one at a time, caused by the breaking of them with the rubbing of his pants and shirt against his back while lying down on his back, or at the act of sitting; in fact, by anything that came in contact with his body. The wound, which was now a deep one, was packed up with oakum, smeared with some sweet oil to prevent it from healing up at the top, and retained there with strips of sticking-plaster. In six weeks the wound healed up finely by granulation; and the patient is now enjoying good health.

Respectfully yours, JULIO J. LAMADRID.

PROCEEDINGS OF SOCIETIES.

THE AMERICAN OTOLOGICAL SOCIETY.

MINUTES FOR 1873.

THE sixth annual meeting of the Society was held at Rice's Rooms, Newport, Rhode Island, July 16, 1873, at 10.30 o'clock A.M.

The President, Dr. HENRY D. NOYES, in the chair.

Present—Drs. John Green, St. Louis; D. D. Pomeroy, New York; J. Orne Green, Boston; Charles I. Pardee, New York; D. B. St. John Roosa, New York; R. M. Bertolet, Philadelphia; C. R. Agnew, New York; Henry D. Noyes, New York; Albert H. Buck, New York; Clarence Y. Blake, Boston; George Strawbridge, Philadelphia; C. H. Burnett, Philadelphia; S. Sexton, New York; William Thomson, Philadelphia; Charles Y. Kipp, Newark, New Jersey; Herman Knapp, New York; Charles E. Rider, Rochester, New York; and, by invitation, Dr. Argyle Watson, New York.

The President appointed Drs. Pomeroy, Strawbridge, and Sexton as the Executive Committee.

Notice was given of a proposed amendment to the by-laws, by striking out the paragraphs referring to the Corresponding Secretary, thereby doing away with the office; and also to change the rule for the meetings so that it should read, "meeting annually, at such time and place as may be determined upon each year."

The Treasurer's report was read, audited, and accepted.

The Executive Committee nominated as members of the Society, Drs. Charles Y. Kipp, of Newark, New Jersey; William Thomson, of Philadelphia; David Webster, of New York; all of whom were duly elected, and Drs. Kipp and Thomson took their seats as members.

The following bulletin of papers was submitted by the Executive Committee, read in order, and referred to the Publishing Committee:

1. Report on the Progress of Otology, Dr. Burnett.
2. Report of Three Cases, Dr. Buck.
3. Tenotomy of the Musculus Tensor Tympani, Dr. J. Orne Green.
4. Therapeutic Value of Tenotomy of the Musculus Tensor Tympani, Dr. Bertolet.
5. Cases illustrating the Effects of Paracentesis of the Membrana Tympani, Dr. D. D. Pomeroy.
6. A Case of Hardness of Hearing for Low Tones, Dr. Burnett.
7. A Peculiar Manifestation of the Paradoxical Formulæ in the Application of the Constant Electric Current to the Right Ear, Dr. Burnett.
8. Tympanic Trephine, Dr. Burnett.
9. Ulceration of the Dermoid Layer of the Membrana Tympani, Dr. J. Orne Green.
10. Reaction of the Auditory Nerve under the Galvanic Current, Dr. Blake.
11. Diagnostic Value of High Musical Tones, Dr. Blake.
12. Case of Deformity of the Auricle the Result of Inflammation, Dr. Roosa.
13. Deafness in Consequence of Epidemic Cerebro-spinal Meningitis, Dr. Knapp.

The thanks of the Society were voted Dr. Burnett for his elaborate and faithful report on otology.

At 2.30 o'clock, after the reading of the fourth paper, the Society adjourned to 4 o'clock.

SECOND SESSION.

The Society was called to order at 4 o'clock by the President, and the minutes of the first session were read and approved. The reading of the papers was then continued till 5.15 o'clock, when, after hearing the ninth paper, the Society adjourned.

THIRD SESSION.

The third session was opened by the President at 7.45 o'clock, and the two amendments to the by-laws proposed at the first session were adopted.

It was voted that one hundred extra copies of the Report on Otology be furnished by the Society to the author of that paper.

The reading and discussion of the papers were then concluded.

The Executive Committee reported the following list of officers for the ensuing year, all of whom were elected:

President,—D. B. St. John Roosa, M.D.
Vice-President,—Clarence Y. Blake, M.D.
Secretary,—J. Orne Green, M.D.
Publishing Committee,—J. Orne Green, M.D.; Charles E. Hackley, M.D.; R. F. Weir, M.D.
Committee on Progress of Otology,—Charles H. Burnett, M.D., and Clarence Y. Blake, M.D.

The same rules in regard to papers, proofs, and adjournment, as last year, were adopted: October 1 being the last day for the reception of articles for publication.

A communication was received from Drs. Blake, Roosa, and Pomeroy, in regard to an International Otological Congress, and, on motion of Dr. Roosa, it was resolved that a committee of three be appointed by the chair, who shall report at the next meeting of this Society as to the feasibility of holding an International Otological Congress in New York in 1876.

The President appointed as such committee, Drs. Roosa, Blake, and Knapp.

The minutes of the second and third sessions were read and approved, and the Society adjourned at 9.45 o'clock.

J. ORNE GREEN, *Secretary*.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-ANNUAL MEETING, June 10, 1873.

Reported by JAMES S. BAILEY, M.D.

DR. ALBERT VAN DERVEER, PRESIDENT, in the chair.

AFTER the reading and approval of the minutes of the last annual meeting, the President remarked, "As the Society increases in numbers, its mortality

must also increase. During the last six months we have been called to mourn the loss of an unusual number by death, and I announce that Dr. John H. Becker died of pneumonia on June 1, aged 45 years.

"As our semi-monthly meetings have ended, I desire at this time to make some acknowledgment for the prompt and efficient manner in which you have given support to these meetings.

"We have held in all ten semi-monthly and two special meetings. These meetings have been uniformly well attended.

"There have been presented, at these meetings, seventeen papers, besides numerous pathological specimens illustrating the subjects considered. Also two important discussions have occupied the attention of the Society.

"In behalf of the officers, I desire to render to you our heartfelt thanks for the generous support you have given us thus far, to elevate our profession and to place our Society among the first and foremost in the State."

Dr. S. H. FREEMAN then rose and pronounced a eulogy upon Dr. Becker, the deceased member of the Society.

Dr. JAMES S. BAILEY, chairman of the committee on publication, presented the report, which, after much discussion, in which Drs. Craig, Porter, Northrop, Swinburne, Quackenbush, and McNaughton took part, was, on motion of Dr. Craig, accepted, and referred back to the committee for further consideration.

Dr. JAMES P. BOYD, chairman of the board of censors, then presented the following names for admission into the Society: James N. Haines, Alma S. Allen, J. H. Blatner, James S. Hill, G. A. Jones, J. H. Hannan, James P. Boyd, Jr., J. Emerson Allen, of Scranton, Pennsylvania, Frank Garbutt, and E. A. Green.

By vote of the Society, they were admitted members upon their complying with the by-laws.

The Vice-President, Dr. A. W. SHILAND, then delivered the semi-annual address.

Dr. FREEMAN moved a vote of thanks to Dr. Shiland for his beautiful address. Adopted.

Dr. JAMES S. BAILEY said that there were several names in the directory who had not paid their yearly dues, and offered a resolution:

"That any member of the Albany County Medical Society who shall be in arrears for two years in paying his yearly dues is not entitled to suffrage in this Society, nor shall he be hereafter reinstated unless back dues are paid, or without a unanimous vote of the Society.

"*Resolved*, That the Secretary obtain the names of such delinquents from the Treasurer and drop their names from the books."

Adopted.

The President then said:

"I would announce the following names as composing the committee called for by Dr. James S. Bailey's resolution regarding the proposed entertainment to be given to Dr. Peter P. Staats: Drs. James S. Bailey, James McNaughton, J. P. V. Quackenbush, S. H. Freeman, John Swinburne, Levi Moore, F. C. Curtis."

Dr. J. M. BIGELOW complimented the Society on the success and interest of their semi-monthly meetings, and offered the following resolution:

"*Resolved*, That the thanks of the Society are due to Drs. James S. Bailey and F. C. Curtis for the able and correct reports which they have written for the *Philadelphia Medical Times* and the *Buffalo Medical and Surgical Journal*, and also to the press of this city for their kindness in noting and reporting our meetings."

Adopted.

VOLTAIRE's definition of a physician is, "An unfortunate gentleman expected every day to perform a miracle: namely, to reconcile health with intemperance."

GLEANINGS FROM OUR EXCHANGES.

A NEW METHOD OF PERFORMING LITHOTOMY (*Edinburgh Medical Journal*, June, 1873).—Mr. A. Davidson, in a paper read before the Medico-Chirurgical Society of Edinburgh, describes and advocates a new mode of performing lithotomy. The staff used is simply a modification of Buchanan's rectangular one, the acute angle being replaced by a gentle curve and grooved on its inner aspect. The form of the external wound is semi-lunar, curved somewhat lower and deeper upon the left side than the right, in order to afford a freer drain on the side in which the prostatic wound is situated. Having exposed the membranous part of the urethra, this is opened, and a guide is introduced along the groove in the staff into the bladder. This guide, consisting of two parallel and connected bars or blades, capable of being separated by means of a screw, forms, when approximated, an instrument about five inches long, somewhat like a female catheter in size, straight, slightly flattened from above downwards, and grooved in the left side so as to permit the bottom point of the knife to slide along without escaping from it.

When this guide has been fairly introduced into the bladder, the staff is withdrawn, and the blades are separated by the screw *to such an extent as to render the tissues tense*. The knife used has a button-shaped extremity to fit the groove in the guide. The blade is narrow throughout, but is slightly triangular, becoming a little broader towards the handle than at the point. This knife is then carried along the groove so as to divide the tense resisting structures, *by its edge being brought into contact with them rather than by actual cutting*. The blades of the guide are now expanded; but should it be found that the required degree of separation cannot be effected without force, the knife may be passed along a second time to cut the structures that still resist. In no case should anything be incised except what is found to oppose gentle dilatation. The size of the calculus determines the extent to which the knife is to be used and dilatation effected. The blades of the instrument, having now been separated so far as the size of the stone seems to demand, serve as a conductor for the forceps, which slip along between them into the bladder. The stone is then extracted in the usual manner. Should the calculus be very large, the knife may be applied in the same way to the right side of the prostate, thus making a bilateral incision; but this is seldom required.

The advantages claimed for this operation are that the incision and dilatation are in proportion to the size of the stone and the resistance of tissues, that the guide for the knife acts at the same time as a conductor for the forceps and diminishes the difficulty of their introduction, and that inflammation of the neck of the bladder and pyæmia caused by bruising, and infiltration of urine, and pelvic abscesses, the result of too extensive incisions, are alike avoided.

PARALYSIS OF THE DIAPHRAGM (*British Medical Journal*, May 31, 1873).—Mr. C. Handfield Jones delivered a clinical lecture on the following case.

E. H., æt. 30, was admitted to St. Mary's Hospital, January 14, 1873. Had been sick two months; had had several severe falls; father had died of hæmoptysis; had had hæmoptysis himself. At the time of admission there was great hyperæsthesia of surface; lung- and heart-sounds good; normal percussion-resonance; upper ribs moved considerably in inspiration, lower ribs and abdomen scarcely moved at all; shortness of breath, aching and shooting pain in the left side; inability to lie down; no cough or expectoration, nor any swelling of the legs; sleeplessness. He was

ordered twenty grains of the saccharated carbonate of iron thrice daily, and ten grains of chloral hydrate at bedtime. He slept somewhat better for the next two nights. The chloral was continued, and he was ordered the following draught three times a day:

℞ Ammoniæ carb., gr. iv;
Ferri ammonio-citratis, gr. viij;
Tinct. nucis vom., ℥x;
Tinct. calumbæ, ℥x;
Aquæ, f℥j.

On the 18th the movement of the abdomen was much increased, and on the 24th the breathing was quite normal. The cure was complete and uninterrupted.

On reviewing the case, the phenomena of a positive kind were dyspnœa, orthopnœa, incapacity for exertion, insomnia, left side pain, altered respiratory movements, and paresis of the diaphragm; of a negative kind,—healthy state of the lungs, heart, and kidneys, and of the vascular system generally. The family history pointed to the probable existence of the tuberculous diathesis, his personal to the possibility of a traumatic lesion of the brain or cord.

The chief symptom was the singular inaction of the diaphragm, especially noticeable as the patient was a male. In considering the causes which are known to produce such inaction we can exclude pleurisy, peritonitis, lead-poisoning, and progressive muscular atrophy, as there was no sign of any of these conditions. Fatty degeneration of the muscle itself could not have existed, as was shown by the result of treatment, and there were none of the recognized features of hysteria. Two possibilities remain: one, that there was actual lesion of the nerve-centres; the other, that the disorder was a paralytic neurosis. The falls which he had undergone might seem to favor the former view; but had there been any contusion of the cord the injury could not possibly have been confined to the nerve-cells connected with the phrenic nerve. The history shows that there was entire absence of any paralysis of the limbs or sphincter. The patient is to be regarded, then, as having suffered a functional paralysis of the centres belonging to his phrenic nerves, from some cause which does not appear, but which is possibly connected with the hereditary tendency to tuberculosis.

Pulmonary Hemorrhage as a Cause of Consumption (*Dublin Journal of Medical Science*, May, 1873).—At a meeting of the Medical Society of the College of Physicians, Mr. J. M. Finny detailed three cases of consumption of the lungs following pulmonary hemorrhage. In all of them the individuals were young, in good health, and able to pursue their ordinary avocations up to the day and hour of the bleeding, and in all the hæmoptysis came on suddenly, without any symptom referable to the chest having been complained of or noticed, and was the starting-point of the future consumptive process. The three cases coincided in the important peculiarity that the lungs did not exhibit, at the time of the initiatory hemorrhage, any signs of previously existing or commencing organic disease, and that it was not until some days had elapsed that the signs and symptoms of pneumonic changes first exhibited themselves. Rejecting the theories that the hæmoptysis was the result of a diseased state of the walls of the arteries of the lungs, or that it was produced by undetected tubercles, Mr. Finny believes that in each case there occurred an accidental rupture of either a bronchial or pulmonary blood-vessel, following some undue exertion on the part of the patient. A portion of the blood was expectorated; but some remained in the smaller bronchi, and, either by gravitation or the inspiratory acts, became lodged in the alveoli of one or more lobules. Here, by its presence as a foreign body or by the retrogressive changes it underwent, it produced inflammation or "acute catarrhal pneumonia," which spread through various parts of the lobes and became recognizable by well-marked physical signs.

The patients perished during the high fever which attended the next step of the morbid process,—the "softening with ulceration" of the inflammatory products.

Abdominal Aneurism successfully treated by Proximal Pressure of the Aorta (*British Medical Journal*, June 14, 1873).—Dr. Headlam Greenhow communicated to the Royal Medical and Chirurgical Society a case of abdominal aneurism, occurring in an able-bodied seaman, æt. 28. On his admission to the Middlesex Hospital a globular tumor was found immediately above the umbilicus, beating forcibly with an expanding lateral as well as with a forward impulse. Its pulsations were arrested by firm pressure over the aorta above the tumor. The patient having been completely anæsthetized, Lister's tourniquet was applied between the tumor and the xiphoid cartilage, and screwed down until pulsation ceased both in the tumor itself and in the femoral arteries. On its first application the pressure was withdrawn after three-quarters of an hour, on account of vomiting, but in two subsequent operations it was retained for from three to four hours. On each occasion the lower extremities became cold and livid; the temperature between the ties was 90°; respirations shallow and gasping, 44 to 56 per minute; pulse 100 to 120; sphygmographic tracings over the radial pulse showed increased arterial tension. These symptoms subsided on removal of the pressure, but for several days the patient suffered much from pain, numbness, and coldness in the lower extremities, and from vomiting, the vomit containing altered blood. The urine was albuminous for two days. The pulsation in the seat of aneurism slowly decreased, until in about six weeks it disappeared entirely, nor was there any distinct tumor remaining; but above the umbilicus was an undefined, somewhat movable hardness. No pulsation could be detected in the aorta from an inch above the umbilicus downward, nor in the femoral, popliteal, or anterior tibial arteries. There had been no return of the trouble, although two years had elapsed, and the man was enjoying perfect health.

Compound Depressed Fracture of the Skull (*Irish Hospital Gazette*, July 1, 1873).—J. Stannus Hughes, M.D., reports a case in which the patient, having had his skull crushed by an accident, suffered the loss of large portions of the occipital and parietal bones. The removal of the fragments brought on a profuse hemorrhage from the longitudinal sinus, followed by the ejection of from three to five ounces of mingled cerebral substance and clotted blood; the brain could be seen pulsating strongly at the bottom of the wound. Contrary to all expectation, recovery was prompt and uninterrupted, except by occasional attacks of retention of urine and of intense priapism. The only permanent trouble resulting from the injury was an equilateral hemiopia, due probably to some lesion in the course of the left optic tract.

Position of Twins (*British Medical Journal*, June 28, 1873).—S. C. Taylor, M.D., writes that in thirteen cases of twins which he has attended the positions were as follows:

Both children with head presentation . . .	6
Both children with breech presentation . . .	2
First child head, second child breech, presentation	2
First child breech, second child head, presentation	1
First child head, second child foot, presentation .	1
First child foot, second child head, presentation .	1
Total number of cases . . .	13

THE VIRTUES OF WHISKY.—The following curious extract from Holinshed's Chronicles, 1577, will be of interest to the advocates of whisky as a therapeutical agent of great power:

"There is used an ordinary drinke of *aqua vitæ*, so qualified in the makyng that it dryeth more and inflameth lesse than other hote confections. One Theoricus (*Episc. Hermenensis juxta Bononiam*) wrote a proper treatyse of *Aqua Vitæ*, wherein he prayseth it to the ninth degree. He distinguisheth three sortes thereof—*simplex*, *composita*, and *perfectissima*. . . . *Beying moderately taken*, sayeth he, it sloweth age; it strengtheneth youthe; it helpeth digestion; it cutteth fleume; it abandoneth melancholie; it relisheth the harte; it lighteneth the mynd; it quickneth the spirites; it cureth the hydropsie; it healeth the strangury; it pounceth the stone; it repelleth grauel; it puffeth awaie ventositie; it kepyth and preserveth the hed from whyrling—the eyes from dazelyng—the tongue from lispyng—the mouthe from snafflyng—the teethe from chatteryng—the throte from ratlyng—the weasan from stieflyng—the stomach from wamblyng—the harte from swellyng—the bellie from wirtchyng—the guts from rumblyng—the handes from shiueryng—the sinowes from shrinkyng—the veynes from crumplyng—the bones from akyng—the marrow from soakyng. . . . *And trulie it is a soueraigne liquor, if it be orderlie taken.*"

MISCELLANY.

HOW TO CURE A COLD.—The whole fraternity of editors, and all of their readers, owe a debt of gratitude to one of their members, the editor of the *Danbury News*, for a report of the following case, instituted by, though not practised himself, but by one of his corps. *Treatment:* He boiled a little boneset and horehound together, and drank freely of the tea before going to bed. The next day he took five pills, put one kind of plaster on his breast, another under his arms, and still another on his back. Under advice from an experienced old lady, he took all these off with an oyster-knife in the afternoon, and slapped on a mustard paste instead. His mother put some onion drafts on his feet, and gave him a lump of tar to swallow. Then he put some hot bricks to his feet and went to bed. Next morning another old lady came in with a bottle of goose oil, and gave him a dose of it on a quill, and an aunt arrived about the same time from Bethel, with a bundle of sweet fern, which she made into a tea and gave him every half-hour until noon, when he took a big dose of salts. After dinner his wife, who had seen a fine old lady of great experience in doctoring, on Franklin Street, gave him two pills of her make, about the size of an English walnut and of a similar shape, and two tablespoonfuls of home-made balsam to keep them down. Then he took a half-pint of hot rum, at the suggestion of an old sea-captain in the next house, and steamed his legs with an alcohol bath. At this crisis two of the neighbors arrived, who saw at once that his blood was out of order, and gave him half a gallon of spearmint tea and a big dose of castor oil. Before going to bed he took eight of a new kind of pill, wrapped about his neck a flannel soaked in hot vinegar and salt, and had feathers burnt on a shovel in his room. He is now thoroughly cured, and full of gratitude.—*The Sanitarian.*

AN ENEMY OF INDIA.—An interesting discussion was recently held in the House of Lords regarding the tigers, which cause such frightful ravages in the East Indies. In Lower Bengal 13,400 persons have been torn to pieces by wild animals in less than six years; and it is estimated that in the whole Indian peninsula 10,000 people perish annually in the same way. In 1869 a single tigress stopped for several weeks the traffic on a road usually much frequented, and made one hundred and twenty-seven victims to her fury. In the Haydunka, from 1867 to 1869, one tiger is credited with killing one hundred and eight persons; and this sanguinary creature counts among his exploits the extermination of a whole family, composed of the father, the mother, and three children. The ravages of tigers among the live stock are naturally enormous. The loss is reckoned at an average of 25,000,000 francs annually. In certain districts emigration has reached considerable proportions. In one central province the inhabitants of thirteen villages fled before a tigress.

The British government has accordingly taken measures for hunting down these enemies of India by a wholesale destruction. It is a little remarkable to find one writer in the London *Times* protesting against the contemplated destruction of tigers, as "wholly unnecessary and unsportsmanlike." He declares that the tiger is not so bad as he is painted, and that the animal is inclined "rather to flee the habitation of man and his presence than to encounter it, far less to court it. Nothing can be more foolhardy and culpable than the way in which the bamboo-cutters, men and women, risk their lives in gaining their precarious livelihood; and these are always the principal victims. They lay themselves out for and tempt, by their solitary habits, the vicious propensities of the animals. Far better to await the completion of the Teheran railway, which will, doubtless, convey sufficient agents of destruction in the shape of our present grouse-shooters to render, in a very few years, our glorious East bare enough of all that exhilarates in the shape of dangerous sport."

ON July 5, ninety-four persons were arraigned at the municipal court of Boston for drunkenness.

In Boston one cannot sell beer, and can sell oxalic acid. In Vienna one cannot sell poison, and can sell beer. We send schoolhouses to Vienna.—*Boston Medical and Surgical Journal.*

DEPILATORY MIXTURE.—A new depilatory mixture is recommended by Professor Boettger, consisting of one part of crystallized sulphydrate of sodium and three parts of prepared chalk. Mixed with water and applied to the skin, it effects the easy removal of hair.—*Med. and Surg. Reporter.*

STATISTICS show that hydrophobia is periodic in character.—*N. Y. Medical Record.*

GLACIAL acetic acid is a good solvent of iodine.

THE U. S. Government having purchased the grounds of the University of Pennsylvania, on Ninth Street above Chestnut, as a site for public buildings, and the new Medical Hall in West Philadelphia not being yet completed, the Trustees have secured, for the use of the Medical Department during the coming winter, the commodious and convenient building formerly occupied by the Pennsylvania Medical College, No. 250 South Ninth Street. All communications should be addressed to

ROBERT E. ROGERS, M.D.,
Dean of the Medical Faculty of the University of Pennsylvania,
250 South Ninth Street,
or P. O. Box 2838, Philadelphia.

DANGEROUS BALLAST.—An "old cruiser" sends us the following account of a fever originating in a naval vessel a few years ago, and traced to its cause. A French frigate, well ordered, with a crew in health, arrived at the port of Cobija, in the desert of Atacama, where, after a few days, a fever known to the French surgeons as the *fièvre pernicieuse* made its appearance and spread in the ship.

As rain is unknown in that district of dry sand, nor any vegetation within leagues, and the vessel in perfect cleanliness, the disease was a surprise. At last it was discovered that a boat-load of sand had been placed in the hold, from which a slight odor arose perceptible to the smell and with a slight astringent effect on the nostrils. This sand, brought from the clear beach, being removed, and the locker cleaned with chlorides, the fever entirely ceased.

At Aspinwall, it is known that a somewhat like result occurs when vessels there take in ballast from the convenient but wet shore-line of the bay. Such vessels generally find fever to break out after having been at sea several days; while the more experienced traders, obtaining stones and dry ballast from a space inland, are for the most part exempt.—*The Sanitarian.*

ELIXIRS.—Pharmaceutists are wild upon the subject of elixirs. A very few of them may be good, some of them may answer for placebos, but a majority of them are worthless. An elixir of wine, beef, and iron sounds well; but I read upon the label of a bottle handed me a few days since, a more captivating title still. It was an elixir of wine, iron, beef, and horseradish. Shade of Epicurus! What stomach could resist it? Tasteless medicine, such as sweet quinine, may have tempted the most wary of us to invest, but experience has taught us they are a great deal like whisky with the "fight" taken out of it, leaving to further distillation only water and burnt sugar. Medicines have an individuality. Aromatics are hot and pungent, tartar emetic produces nausea, quinia is bitter, and if it must be changed it is quite as well to make it more bitter still, because all these qualities are agencies in the relief of disease. —*President's Address before the Ohio State Medical Society*, 1873.—*The Clinic.*

THE *Michigan University Medical Journal* ended its career with the number for April, 1873.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 22, 1873, TO JULY 28, 1873, INCLUSIVE.

WOODHULL, ALFRED A., ASSISTANT-SURGEON.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 131, Department of the South, July 23, 1873.

BROOKE, JOHN, ASSISTANT-SURGEON.—Relieved from requirements of par. 2, S. O. 78, c. s., from these Headquarters. S. O. 87, Department of the Columbia, July 12, 1873.

PHILLIPS, H. J., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon, Camp Warner, Oregon. S. O. —, Headquarters Department of the Columbia, "in the field," July 8, 1873.

LIPPINCOTT, H., ASSISTANT-SURGEON.—Assigned to duty at Camp Lowell, Arizona Territory. S. O. 53, Department of Arizona, July 8, 1873.

KING, W. H., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Woodhull, assigned to duty at Yorkville, South Carolina. S. O. 131, c. s., Department of the South.

PHILADELPHIA MEDICAL TIMES.

SATURDAY, AUGUST 9, 1873.

ORIGINAL COMMUNICATIONS.

A FATAL CASE OF CONGENITAL TRACHEO-ŒSOPHAGEAL FISTULA.

BY D. S. LAMB, M.D.,

Acting Assistant-Surgeon, U.S.A.

THE patient in this case was seven weeks old at death, March 31, 1873. From its birth almost every attempt at nursing was attended with strangling, and sometimes with lividity of skin. The mother stated that during a portion of the previous summer she had been roughly treated by her husband while he was intoxicated; on several occasions he had violently choked her.

I saw the child for the first time about sixty hours before its death. The most prominent symptom was flatulence, which was abundant, and very painful; there was no vomiting, but there were several thin, greenish stools daily; it nursed but little. The respirations were very hurried, numbering at one time as many as seventy per minute; each respiratory effort was attended with a to-and-fro movement of the head. The cough was slight, infrequent, short, hacking, sometimes provoked by the strangling; occasionally a little froth was brought to the lips, but never thick or dark sputa or blood. The nares were dilated at each inspiration; the mouth was sometimes opened to breathe more easily. He was drowsy much of the time. As a rule, the skin of the trunk and extremities was warm, smooth, and not dry; there was no *pungent* heat; the head at times showed some moisture; the pulse was frequent; the tongue coated thinly whitish.

At the autopsy, a small granular deposit was found upon the mucous membrane of the trachea, just below the fistulous opening; it was suspected to be from a milk-clot, but was washed off and lost before its composition could be made out with certainty. The right lung was very dark and hepatized throughout; there was also slight pleuritic adhesion between the upper and middle lobes; no fluid or lymph in the cavity. The left lung was somewhat emphysematous in the superior lobe; the anterior lower margin to the extent of about a square inch was in the same condition as the right lung; there was neither fluid, lymph, nor adhesion in the left pleura. The heart was normal. Stomach and intestines distended with flatus. Liver, spleen, and kidneys normal. Mesentery somewhat congested.

The head was not examined, except so far as to notice the condition of the palate, which was found normal.

The hyoid bone, larynx, and portions of the trachea and œsophagus were removed. In the median line, nearly half an inch below the lower border of the cricoid cartilage, was a fistulous communication between the two tubes, having a longitudinal diameter of three lines and a transverse diameter of one line; the direction of the fistula was downwards and backwards, the opening in the œsophagus being at a lower level than that in the trachea; the edges were smooth and rounded, and the mucous membrane normal. The danger of passage of the contents of the œsophagus into the trachea appears to have been guarded against to some extent by the close apposition of the walls of the fistula.

This specimen was contributed to the Army Medical Museum, and is exhibited as Number 1161 of the Medical Section. To show the fistula more distinctly, a whalebone probe was introduced, and the hardening action of the alcohol used as a preservative fluid has rendered the fistulous opening permanently dilated.

I believe this form of defective development of the trachea and œsophagus to be extremely rare. *I have not found any such specimen described either in the museum catalogues or works on pathological anatomy or teratology to which I have had access.*

It does not belong to what have been called "congenital fistulæ of the neck," originally described by Dzondi and Ascherson, since these fistulæ have *external* communications, either asymmetrical (usually in the median line) or symmetrical, close by the internal insertion of the sterno-mastoid muscles; these also have the internal communication with but one tube, either the trachea or œsophagus, never with both in the same case; and sometimes, indeed, the communication with either tube is problematical. Again, these fistulæ have never been recorded as endangering life. (See "The British Record of Obstetric Medicine and Surgery for 1848," published at Manchester, England, and edited by Charles Clay, M.D. Also, "Die Missbildungen des Menschen," by Dr. Förster, Jena, 1865, page 101.)

Probably it should be classed along with those congenital tracheo-œsophageal fistulæ with which are conjoined other malformations of the œsophagus, as, for instance, cul-de-sac termination; but classed as a *variety* in view of the absence of any such complication.

A specimen of "cul-de-sac from a case of imperforate œsophagus, in which the upper portion of the tube terminated on a level with the bifurcation of the trachea, the lower portion of the œsophagus communicated above with the posterior surface of the bifurcation of the trachea," was obtained by me at an autopsy made for Surgeon C. H. Laub, U.S.A., and appears as Number 812, Medical Section, Army Medical Museum. This case was published in the Museum Catalogue, Washington, D.C., 1867. The child lived to be eleven days old; was said to have been able to swallow small quantities of liquid, which produced a gurgling sound in passing through the trachea.

The specimens of congenital deficiency of the neck or its contained viscera, or of the thoracic portions of the trachea or œsophagus, so far as I have found them described in museum catalogues, are very few in number, and all belong to *one* class, viz., *cul-de-sac pharynx or œsophagus*, with or without fistulous communication with the air-passages.

In the Catalogue of the Museum of the Army Medical Department, Fort Pitt, Chatham, London, 1845, page 385, is described as Specimen 2707, "Œsophagus wanting, the pharynx terminating opposite the cricoid cartilage. Taken from an encephalous fœtus."

The Catalogue of the Museum of the Royal College of Surgeons of Ireland, Dublin, 1834, Anatomy, volume i. page 152, describes as Specimen G, a. 53, "A case of malformation of the pharynx and trachea in an infant. The pharynx, which is unusually wide, terminates below in a cul-de-sac, without having any connection with the œsophagus. The œsophagus takes origin from the posterior wall of the trachea, by an opening which is so smooth and wide as to render the passage from the larynx into the stomach as direct and easy as that along the trachea into the lungs. See Dublin Hospital Reports, volume v. page 310.—J. H."

The Catalogue of the Royal College of Surgeons of England, London, 1872, Teratological Series, page 91, describes as Specimen 394, "The tongue, pharynx, trachea, and œsophagus of a human fœtus, with a small portion of the diaphragm and stomach. The œsophagus opens into the trachea just above its bifurcation; it is not connected with the pharynx. The trachea has been opened in front, and a green-glass rod has been inserted into the œsophagus."

395. "A similar preparation from a new-born child, in which the lungs and stomach are also preserved. The œsophagus is united with the pharynx by a muscular band."

396. "A similar preparation from a human fœtus; the lungs are abnormal in form, and have not been inflated with air."

In the Catalogue of the Dupuytren Museum ("Manuel d'Anatomie Pathologique" of Ch. Houel, Paris, 1862, page 778) is described as Specimen 51, "Small child, which lived three days; the œsophagus terminates at its middle part in a cul-de-sac; the lower part communicates with the bronchi."

The Catalogue of the Brolik Museum, Amsterdam, 1865 (Anatomy), page 442, describes as Specimen 311, "Œsophagus and trachea of a child who lived only five days. It could swallow nothing; all it took was rejected, and intermixed with air-bubbles. A little above the origin of the bronchi, the œsophagus terminates in a blind sac; a little lower it is renewed, to open soon into the stomach. The blind sac of the upper part communicates by an oval opening with the trachea. The separation between the œsophagus and the trachea, which is developed from a simple primordial canal, has taken place only imperfectly. Plate xcvii. [xcix. ?], Figures 2 and 3."

The Catalogue of the Boston Society of Medical Improvement, Boston, 1847, page 128, describes as Specimen 456, "Malformation of the œsophagus, from a patient of Dr. Walter Channing. Superiorly, the canal can hardly be said to exist, as it terminates at once in a cul-de-sac behind the larynx; inferiorly, it opens freely into the trachea, just above the bifurcation, but below this it is sufficiently well developed. The child lived five days, and died, at last, apparently from pneumonia, every attempt to swallow liquids causing great distress, with lividity, and almost suffocation. 1839."

Also, 457, "A second specimen, similar to the last, from a patient of Dr. J. Bigelow. The child was born at the full period, and well developed. On the second day it was observed to take the breast with avidity, but after a few minutes seemed to vomit; liquids also when put into the mouth were immediately rejected; this continued, with much distress and an increasing emaciation, till the eighth day, when it died. Occasionally the respiration was obstructed by a kind of spasm, and there was constantly heard over the chest a mucous, and towards the last a subcrepitant, râle.

"The upper part of the œsophagus is large, quite muscular, and terminates in a cul-de-sac about opposite the middle of the trachea. The lower portion, which is smaller, opens freely into the trachea just above the bifurcation. The stomach was much distended, containing a considerable quantity of brown, viscid fluid, and a large quantity of extremely viscid mucus, which adhered almost everywhere to the inner surface, the membrane itself being softened, as if by the action of gastric juice. The whole of the left lung, except a trace of healthy tissue at the base, and about one-third of the lower lobe of the right lung, was in a state of the most complete apoplexy, looking like a mass of black-currant jelly. The uterus was malformed, and the vagina entirely wanting, though there was nothing unusual in the external organs. It was found, also, that the common trunk of the left subclavian and jugular veins entered the right auricle by a separate opening, instead of uniting with the vena cava. The other organs were well formed.

"It is remarkable that this malformation of the œsophagus, which is, according to M. Andral, quite rare, has been met with in two other cases, at least, in this neighborhood, one of them terminating in eight days, and the other in about twenty-four hours."

The following catalogues contain no specimens of congenital deficiencies of either the trachea or œsophagus:

St. George's Hospital, London, 1866.

St. Bartholomew's, London, 1846 to 1852.

Guy's Hospital, London, 1863.

Army Medical School, Military Surgery, London, 1867.

Royal College of Surgeons, Edinburgh, 1834, Part I.

Thibert Museum, Paris, 1860.

Strasbourg, 1843.

Leipzig, 1819.

Vienna University, Human Anatomy, Vienna, 1869.

Braunschweig, 1854.

Warren Anatomical Museum, Boston, 1870.

New York Hospital, New York, 1860.

Pennsylvania Hospital, Philadelphia, 1869.

I wish to call attention to a similarity in cause of death in several of the cases just described. The two cases from which were obtained Specimens 456 and 457, Bost. Soc. Med. Imp., appear to have ter-

minated fatally from *pneumonia*, as did the case reported by me. In Case 456 there was great distress, with lividity and almost suffocation, on attempting to swallow. In 457 there was also much distress, occasionally a kind of spasm of the respiratory muscles, and mucous râles heard over the chest. At the autopsy the lungs were found in a state described as *currant-jelly* hepatization. This term would very well fit the condition of the lungs in the case reported by me.

It seems quite possible for fluids to find their way into the trachea of an infant, even without any obstruction of the œsophagus. In the *Lancet*, London, May 10, 1873, page 669, is an account of the case of a child, aged "one year, which was fed by the bottle, put to bed at six o'clock, and died at midnight with all the signs of intense dyspnœa. At the post-mortem examination (ten hours after death) the two lower lobes of the lungs were found quite softened, grayish, having a smell of butter, and, in a word, having undergone the action of gastric juice. Altered milk was found in the trachea and bronchi. In this case the milk contained in the stomach, and which, doubtless, had been taken in excess, was vomited, and, on account of the horizontal posture, had penetrated into the air-passages.

"Dr. Parrot drew the attention of his colleagues to the importance of the fact from a medico-legal point of view. He thinks that this occurrence must be rather frequent, as he has already witnessed two cases in his own sphere of observation."

Dr. Förster (loc. cit.), describing the cul-de-sac œsophagus, states that the malformation "is observed in usually well-formed individuals, that the œsophagus in its upper part ends blindly, and thence to the cardia appears only a solid cord; sometimes the upper and lower part of the œsophagus exists but the middle is wanting, and is replaced by a solid cord (Plate xxiv., Figure 19). In other cases the œsophagus ends in its upper third blindly, and forms with the pharynx a diverticular pouch, but at the same height with the blind end of this pouch, or perhaps a little lower down, the œsophagus continues, but opens above into the posterior wall of the trachea (Plate xxiv., Figures 17 to 22). All these defects shut off viability, and the suckling dies the first day after birth [one case above reported lived *eleven* days]. They depend partly upon an arrest of development of the œsophagus at the stage of development in which it was yet solid, partly upon an incomplete separation of the trachea from the œsophagus with which it originally cohered."

Rokitansky, Pathological Anatomy, Vienna, 1861, volume iii. page 128, considers the cul-de-sac pharynx conjoined with a communication of the œsophagus with the trachea as the result of a destructive process in the fœtus.

Andral, Pathological Anatomy, Brussels, 1857, volume i. page 474, refers to a case reported by Astley Cooper "in which there was complete absence of the œsophagus, the pharynx terminated in cul-de-sac, and the stomach was without cardiac orifice; the child lived *eight* days."

In conclusion, I would refer to the following works for interesting discussions of the subject of cul-de-sac œsophagus:

J. H. Hebers, Pathological Anatomy, Bonn, 1839, volume ii. pages 142 and 295.

E. Klebs, Pathological Anatomy, Berlin, 1868 to 1870, page 164.

Ch. Houel, Pathological Anatomy, Paris, 1862, pages 445 and 495.

Thomas Hodgkin, Morbid Anatomy, volume ii. Part I., London, 1840, page 247.

M. C. Billard, Diseases of New-Born Infants, Paris, 1833, page 494.

Hermann Lebert, Pathological Anatomy, Texte II., Paris, 1857 to 1861, page 157.

I have not found either in St.-Hilaire or Serres anything bearing especially upon the subject of this paper.

THE USE OF ATROPIA IN OPIUM-POISONING.

BY DR. H. C. WOOD, JR.,

Clinical Lecturer on Diseases of the Nervous System in the University of Pennsylvania.

THE following case and remarks were sent to me just as given below, by Dr. Robert F. Brooks, of Carthage, Missouri, and seemed to me of such interest that, with his consent, I have sent them to the *Philadelphia Medical Times*. He wished from me an opinion and answers to his inquiries; and perhaps it may not seem egotistical if I give them in print.

In the first place, it is extremely probable that the oak bark, either by its action upon the mucous membrane, or by forming a tannate of the alkaloid, was the cause of the long delay in the production of symptoms by the morphia. In regard to the use of atropia, it seems to me to have been in a great measure judicious.

The point at which to cease the exhibition of the atropia is always a most delicate one to decide; and I can offer no infallible guide. It should not be forgotten that the contraction of the pupil in the advanced stage of opium-poisoning is not due solely to the drug, but also to the accumulation of carbonic acid in the blood from impaired respiration. It is by no means certain that atropia and carbonic acid are antagonistic, even in the sense that atropia and morphia are. Further, the weight of the present evidence seems to me to be in favor of the view that morphia and atropia are not, as regards the pupil, antagonistic. By this I mean that morphia causes contraction by acting on the nerve-centres, atropia, even when injected into the blood, dilatation, by acting locally upon the peripheral nerves of the eye, just as when dropped into the eye. If this be so, it is evident that the state of the pupil does not afford any sure indication as to which drug is influencing most powerfully the nerve-centres.

I do not myself believe the condition of the pupils should be allowed to determine the question as to the further use of the counter-poison, but that the judgment should be made up by surveying the

whole field,—the condition of the respiration, the tendency of the symptoms to become worse or better, the depth of the coma, etc., etc., all being taken into consideration. The cardinal principle *not to give more atropia than is absolutely necessary* should never be lost sight of. Thus, in the present case, as respiration had advanced from naught to ten times a minute, I think it would have been more judicious not to have given the last two injections of atropia, but to have waited to see if the respirations would not rise still more without its further exhibition.

Some experience has shown us that the effect of atropia in these cases, where it once fairly becomes apparent, goes on increasing, so that it may be some hours after the last injection before the mydriatic symptoms are developed in their fullest intensity.

Indeed, in the present case the very noticeable circumstance that the respirations finally rose to double their normal frequency renders it highly probable that the two last injections were unnecessary; and if they were unnecessary they were harmful. If the patient had been a robust man, he very likely would have recovered, as death evidently was due not directly to the poison, but to a secondary exhaustion, coming on after, probably, a large portion of the alkaloid had been eliminated. In conclusion, it is perhaps allowable to call attention to the very striking confirmation which the case affords of my opinion, or belief, that atropia does good in opium-poisoning by acting upon the respiratory centres.

CARTHAGE, MO., June 30, 1873.

On the evening of June 27, 1873, I was called four miles in the country to see Mr. Jackson Gates, a thin tall man, aged 65, nervous, dyspeptic for twenty-five years, whom I found suffering from an attack of cholera morbus. He had cramps of legs, and pain in belly, and was trying to keep from evacuating his bowels, as he fancied the frequent stools (as of soap-suds) made him very weak. He said he had taken nothing but a draught of infusion of oak bark.

I arrived at 9.40 P.M., and during the next hour gave him three doses of sulph. morphia,—in all, between three-quarters of a grain and one grain. I now made up seven papers, each containing $\frac{1}{8}$ gr. morph. sulph. and $\frac{1}{4}$ gr. opium, and gave directions to give one at 11 P.M., and every hour afterwards if his distressing symptoms continued; to stop the medicine if he was at ease or slept.

Returned the next morning at eight o'clock, and found him drowsy, though easily wakened. Pupils not contracted, the conjunctiva red, and excessive itching of the skin. His son, who nursed him, had given the medicine every hour, and had judged it best to give six of the powders, stopping at 5 A.M., or four hours before my second visit. I left him a tonic, and returned home suspecting nothing.

I was recalled just before one o'clock in the afternoon, with the news that my patient could not be wakened, and on arriving, at 1.40, found that he had become quite drowsy at 9 A.M., and could not be waked after 10 A.M., getting worse and worse. His pupils were mere points; his respirations from 2 to 3 per minute, and stertorous; his pulse less than 60; his skin purple; his finger-nails black.

I quickly dashed several pailfuls of cold water, with force, on his bare face, neck, breast, shoulders, and belly, called him loudly, and roused him so that he begged us to quit. We made him get up and walk, one on each side of him; made him swallow several tablespoonfuls of freshly-ground mustard, a teaspoonful of sulphate of zinc, a tablespoonful of powdered ipecac, and a good deal of warm water. And now, as he refused to walk any more, and commenced to fall down asleep, we again dashed cold water on him, and made him move on. After this he began to be nauseated, and was enough awake to propose to put his finger in his throat so that he might vomit. In this manner we succeeded in getting him to vomit quite freely. At 5 o'clock we began to give him strong coffee, and he got better, yet needed continual nudging and washing of the face with cold water to keep him awake.

Towards 7 o'clock P.M. I obtained the following solution:

℞ Atropiæ, gr. j,
Acid. acetic., gtt. viij,
Aquæ, ℥j. M. Fiat solutio.

and gave, hypodermically, at 7 P.M., gtt. vij.

His pulse now was 60; at 7.26 pulse 108, and pupils slightly dilated. As the atropia solution dropped from the bottle, one drop proved to be equal to $\frac{1}{3\,3\,6}$ gr., or 8 gtt. $= \frac{1}{4\,2}$ gr.

He now seemed a little better.

Second injection, of gtt. viij, at 9 P.M. Pulse 102, and pupils dilated a little more. Is taking coffee, yet grows worse rapidly.

10.30 P.M.—Douche, walking, shaking, etc., fail, and he can take no more coffee. The atropia acted so feebly that I was discouraged, and did not press it.

At 10.30 P.M. I laid him on a bed and used artificial respiration and jerking for half an hour, when he began to breathe at the rate of eight times a minute.

Third injection, of gtt. x, 12.49 A.M., Sunday, 29th.

3 A.M.—He will not breathe except by jerking, and so continued until afternoon at 3.15 P.M., we all the while staying by him and regularly jerking his body one-fourth circle over at the rate of eight times a minute.

At 3.13 A.M. gave fourth injection of gtt. x.

At 5.45 A.M. pulse 108, and pupils dilated to say twice their natural size.

Fifth injection at 6 A.M., of gtt. x.

I now went home to get a catheter, and happened to think of Dr. H. C. Wood's article in the *American Journal of the Medical Sciences* for April, 1873, as to the use of atropia in cases of opium-poisoning. I eagerly read it, and resolved to press the atropia till I made my patient breathe.

Returned before 9 A.M., and found my patient livid, and that his attendant had been rolling and jerking him assiduously, hardly able to keep his breath in him.

Sixth injection, of gtt. xij, at 8.52 A.M.

Catheterize (enema of whisky ℥ij, milk and egg) at 9.30 A.M.

Seventh injection, of gtt. xij, at 10 A.M.

At 10.30 enema of whisky ℥ss, with milk and an egg. Forced respirations, eight to the minute.

Eighth injection, at 11.8 A.M., gtt. xij. Enema at 11.30 A.M. Am sure by this time that atropia helps his breathing; that is, one need not jerk him so hard to keep him breathing. Pulse of more jerking character.

Ninth injection, at 12 o'clock, of gtt. xij.

Tenth injection, at 1 P.M., of gtt. xij. Enema at 1.30.

Eleventh injection, of gtt. xij. Respirations same. Pulse 108. Enema at 2.40 P.M. Now breathes a little by his own effort, anticipating the monotonous jerking. Pupils do not dilate any more, but stay about twice the natural size.

Twelfth injection, of gtt. xij, at 3 P.M., and at 3.15 P.M. respires voluntarily, at eight times a minute, for the first since 3 A.M. Respirations not stertorous.

He now has twitchings of the muscles, especially of

the shoulders, then of arms, then of chest, and notice when they twitch he at once gasps for breath.

Enema at 3.45 P.M. Pulse 108. Respirations 10.

Thirteenth injection, of gtt. xij, at 4.9. At 5.10 P.M. respirations 12, pulse 108.

At 5.50 P.M. fourteenth and last injection, of gtt. xij. Pulse rises to 120 a minute, and seems weaker. Respirations 12 to the minute.

At 6.30 P.M. use catheter, and then give enema of whisky, etc.

At 7.45 P.M. respirations 16. Enema at 8.30 P.M.

At 10, 12, and 2 o'clock in the night has so much fever that I only give enemata of milk and water. His trembling increases, and before 4 A.M. he coughs and commences to groan, and then to move a little.

At 4 A.M. pulse weaker, 120, and intermits. Give enema of ℥ss whisky, etc. He now continually trembles and jerks. All enemata are retained till we use the catheter at 6 A.M., when he evacuates the bowels.

Between 5 and 6 A.M. of 30th begins to swallow: so we give, by the mouth, water, milk, whisky, and broth. He now begins to call out in delirium; opens his hitherto closed and dead-looking eyes; looks wildly here and there; sets the dog after the pigs, and so on. Respirations 36 to the minute; color natural. From this time we endeavor to keep up his strength by stimulants, broth, milk, and enemata of milk, but to no purpose. He grows worse, collapses at 4 P.M., and dies at 5 P.M. Two hours before death his pupils widely dilate.

Remarks.—During Sunday, June 29, while using atropia, face and neck were scarlet color. On weighing specimen of opiate given, I concluded that he could not have taken, from 9.40 P.M., 27th, till 5 A.M., 28th, or seven hours and twenty minutes, more than gr. 1¾ of sulph. morphia, and gr. 1¼ opium.

The twitchings of muscles and delirium followed the use of the atropia; yet the last atropia was used before 6 P.M. of the 29th, while he did not become delirious until 5 A.M. of the next day. As soon as the injection was given, the skin began to sink to its natural level, and soon afterwards appeared natural.

Did the atropia accumulate and overwhelm the system? How tell when you have given enough? Stillé, vol. i. p. 743, 2d ed., says, "Pupil is an infallible index," etc. Here it was not. My guide was the waking of the respiratory centres: when I was sure he could breathe well, I stopped using the atropia.

Could the infusion of oak bark spoken of have astringed the walls of the stomach to such an extent that the morphia could not be absorbed for several hours, except in very small quantity?

I have calculated that nearly one-half of a grain of atropia was injected.

ROBERT F. BROOKS, M.D.

A CASE OF FRACTURE OF THE SKULL.

Reported by EMORY ESHLEMAN, M.D.

ON the 18th day of July, 1872, Mr. W. S., while following his usual occupation, horse-shoeing, received a violent kick on the head from a horse in proximity to the one upon which he was engaged. Immediately succeeding the occurrence of the accident, two homœopathic practitioners of medicine and surgery, named respectively Stiles and Middleton, drove to the door, and, of course, had their attention called to the injured man, who was lying bleeding and unconscious on the ground. He in a few moments, however, became so far conscious as to inform those around him of the number of his house. Under the direction of these medical (?) gentlemen, he was immediately placed in a carriage and conveyed to his home, no effort having been made, upon their part, even to arrest the hemorrhage, which, from all accounts, must have been profuse. Arriving at the house of the injured man, these gentlemen immediately made an examination of the condition of affairs, and, after using the probe quite freely, informed his anxious wife, in answer to her interrogatories, that the skull was not fractured, neither, in their estimation, had any serious damage been done to the brain. The injured man, however, said, "My skull is broken, and it is all up with me." He now also, for the first time, became conscious that he was utterly unable to move in the smallest degree any portion of the left half of his body, and asked these gentlemen the cause of this difficulty. He was assured by them that it was a matter of no significance whatever, but resulted from his having lain on that side in his journey from the shop, and that the side was in consequence "asleep or numbed."

After completing the examination, the edges of the wound in the scalp were drawn together and held in apposition by the interrupted suture. Ordering the free application of tincture of arnica to the wounded head, and bottles of warm water to relieve the condition of the left side (paralysis), they took their departure.

Husband and wife, being very much dissatisfied with both the opinions and treatment of these gentlemen, whom most unfortunate circumstances had forced upon them, soon after called upon me.

Upon my arrival I found an incised wound of the scalp, fully four inches in length, occupying the right parietal region, clumsily drawn together by very coarse silk sutures. The man was perfectly conscious, and complained of great pain in the head. There was marked facial paralysis of the left side, and intimated complete hemiplegia of the whole left side of the body.

Having already seen enough of the case to convince me that grave and serious injury had been sustained by both skull and brain, and that there was, in all probability, a depressed fracture of the skull resulting in compression of the brain, I informed the family concerning my apprehensions, and, at the earnest solicitation of the friends, consented to take charge of the case, promising nothing favorable as to the result. Upon introducing the probe through the gap in the scalp, I found the skull depressed as far as the instrument could be carried on either side of the wound. On account of the responsibility of the treatment of this case, my cousin, Dr. J. S. Eshleman, was called in consultation, upon whose arrival the sutures that held the wound together were cut. Immediately beneath the scalp I found several small fragments of brain-substance. Upon introducing that best of all

probes, the finger, abundant proof was afforded of the diagnosis,—a very extensive depressed fracture, confined to the right parietal bone. I could feel distinctly the rough edges of broken bone, and, running the finger along these, could form some idea of the magnitude of the injury. The surface of depressed bone seemed to be about three inches square, and was in three distinct portions. One of these portions, triangular in shape, and occupying a position near the frontal extremity of the bone, seemed to be completely separated from its connection with the surrounding bone. The size of this fragment was one inch in length and three-fourths of an inch in width at its base. In regard to the other two pieces, although depressed in such a manner as in some places to show the whole thickness of the unbroken skull standing above them, the fact of their complete detachment could not be determined. These two pieces were much larger than the one described as triangular.

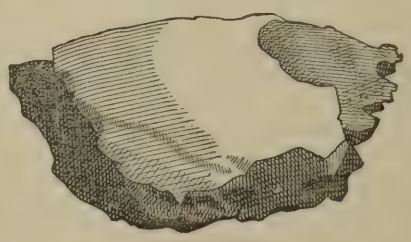
Having now determined the true condition of affairs, it was decided to relieve the injured brain immediately of the great pressure to which it was subjected; and, the patient being anæsthetized, the piece of bone previously spoken of as the triangular one was removed by the ordinary lever belonging to the trephining-case, with some difficulty, although completely detached.

The peculiar manner in which this portion, in common with the others, was driven under and held by the surrounding unbroken skull, rendered its removal very difficult, and made it necessary to enlarge the wound in the scalp one inch. Profuse hemorrhage followed the removal of this portion; and, ice failing to arrest it, bits of lint saturated with Monsel's solution were carefully introduced into the opening, and the bleeding was soon under control. Attention was now directed to the second depressed portion of bone. This was about two inches in length by one inch in width. Its connection with the skull at its occipital end, although not quite severed, was so slight as to make its separation in time a certainty. Owing to its large size, and fearing that the force necessary to effect its detachment from the dura mater and from the skull proper would be followed by a recurrence of exhaustive hemorrhage, it was deemed advisable simply to elevate this larger piece and allow nature to effect its separation. This was with but little effort accomplished.

The third portion, also greatly depressed at its free end, required quite a good measure of force to effect its elevation. The line of fracture extended some distance under the sound scalp in such a manner that its extent could not be determined. It was evident, from the difficulty experienced in its elevation, that its connection must be rather firm, which encouraged the hope that the periosteum remained intact over the greater portion of the line of fracture. The brain was now exposed to view, and could be distinctly seen to rise with every pulsation of its arteries. Both its membranes and substance were somewhat lacerated, as was evinced by the presence of brain-matter outside the broken skull prior to any operative interference. However, close and satisfactory inspection of the brain and its surroundings was precluded by the blackening produced by the application of Monsel's solution. Our patient by this time began to show symptoms of exhaustion, calling for moderate stimulation. The scalp-wound was gently supported by several adhesive strips. We directed the application of cold water to the head, and on the following morning applied ice-bags, which were kept constantly to the head for three weeks. Morphia was quite freely administered for the relief of pain. Complete hemiplegia persisted until the beginning of the second week, when he was able to move the index-finger, and in a few days more could use the arm sufficiently to fan himself. In about three weeks he could, with but little assistance, walk about his room, and in six weeks walked with ease a half-dozen squares. There was no fungus of the brain.

One week after the occurrence of the accident he had marked erysipelas of the left ear, which, under treatment, subsided without involving the wounded head. There was at no time any very marked evidence of cerebral inflammation, although for several days the temperature was elevated and the pulse accelerated. It may be that the profuse hemorrhage in some measure prevented serious inflammatory action. For some days the bowels refused to act, but under purgatives and full enemata they were freely moved, and remained regular.

The second fragment, whose removal was not at the time considered advisable, remained in the position in which it had been placed. The process of separation was carefully watched, and on the 16th day of September following, about eight weeks after the reception of the injury, was perfectly free so far as bony attachments were concerned, but retaining in a slight measure its connection with the dura mater. Dreading hemorrhage, a silver probe was gently insinuated underneath the bone and the dura mater easily peeled from its under surface, and this large fragment, two inches long and one inch



PIECE OF BONE.

wide, readily removed with the dressing-forceps. No bleeding followed the removal. The sudden removal of so large a portion of the skull gave to the man, as he at the time said, the sensation that he had "lost the roof off his head," and for several days it was impossible to induce him to get off his seat, even to go to bed, for fear his brain would "jump out." His wife informs me that he passed three nights in the chair. In the course of a week he became accustomed to the loss of pressure, and walked about as usual. The wound healed slowly, in consequence of the gradual exfoliation of bone, very small por-

tions coming away weekly. The left side has gradually increased in strength, until now at this date (July 1, 1873) it would be impossible for any one unacquainted with the man's history to perceive any difficulty in walking. The opening in the skull has gradually closed, and is now covered over with a cartilaginous substance. Of course a considerable depression remains at the seat of the removal of bone.

The third portion of bone, which was much larger than either of the others and required so much force to effect its elevation, justified the impression formed at the time, that it was not so nearly separated but that it might remain, by becoming firmly united to the adjoining portion of the skull. There has been no tendency to epilepsy.

This man's skull measured fully three-eighths of an inch in thickness. Mr. S. has for some time been employed in the establishment of Messrs. Powers & Weightman, doing full work.

In conclusion, it seems proper to express the opinion that the good result of the case would not have been achieved without the operative interference which has on various occasions been denounced by the gentlemen of the invisible globules.

TRANSLATIONS.

WERNICH ON AN ADDITIONAL EFFECT OF ERGOT, OF IMPORTANCE TO THE OBSTETRICIAN.

Translated from the *Centralblatt für die Medicin. Wissensch.*

BY DR. WM. ASHBRIDGE.

THE results of a large number of experiments, and the frequent mention of a "distended bladder," occurring in the reports of post-mortem examinations, show that the fulness of the bladder found in patients under the influence of ergot is not merely an accidental concomitant of the exhibition of this drug. The explanation of this does not seem far to seek, since the strongly irritant action of the preparations of ergotin upon the sphincter vesicæ is not only a recognized fact, but one that is frequently availed of in therapeutics, in paralysis of the sphincter muscle after typhus, in wetting the bed in children, in the incontinence of the aged, due to simple weakness of the sphincter, in the paralysis of the same muscle in those suffering from paraplegia, etc. But from the circumstance that in animals used for experiments to determine the action of ergotin upon the uterus, in which the bladder, from motives of convenience, had been previously emptied, but yet soon after the administration of the drug was found full of urine, we suspected that in addition to spasm of the sphincter there was still another effect produced by the ergot. This suspicion was strengthened and brought almost to a certainty by the repetition of the same phenomena almost without exception; and, without going into the question whether the increased blood-pressure caused by ergotin is enough to account for the phenomena observed, Wernich feels justified in stating, in opposition to Drasche, that the fulness of the bladder observed after the administration of ergot is due not only to a retention of the normal amount of urine, but also to an increased amount of secretion of that fluid.

Two cases are adduced by Wernich in illustration of his views. The first was a primiparous woman in labor with twins. After the birth of the first, the bladder emptied itself spontaneously, the os uteri was fully dilated, and the head of the second child presented, but, owing to a cessation of labor-pains, ergot was given at intervals of half an hour during the next three hours. The uterus contracted fully, but the head did not advance. At the return of the doctor the bladder was found very full. It was emptied, and almost immediately the child was born.

The second case was also a primiparous woman, in whom there had been a complete cessation of the pains for some hours; and, as the patient and her friends had a great dread of the forceps, recourse was had to ergot, given in the same dose and at the same intervals as in the previously described case. After the second dose the pains came on, gradually increasing, but by the end of the second hour had not caused the head to advance. The bladder was seen to be greatly distended, and by means of the catheter a large amount of clear urine was drawn off, and at once the head advanced, the forceps were applied, and a male child of normal size extracted.

This is scarcely a matter for the obstetrician, as at all events, before any operative interference, the bladder would be examined; but it is worthy the attention of the assistants of the lying-in woman.

It would be advisable for them to use the catheter after a prolonged ineffectual administration of ergot, as it is quite possible that in many of these cases in which want of power has been attributed to the drug, a contrary verdict would have been rendered had the precaution to relieve a distended bladder been observed.

GRAVE ACCIDENTS CAUSED BY THE APPLICATION OF CHLOR-HYDRATE OF ANILINE IN PSORIASIS.

By Dr. Lailler. Translated from *L'Union Médicale*, No. 67, June, 1873,

BY JEAN PAUL BONSIEUR, M.D.

THE resistance of psoriasis to external remedies is well known. A long list of all kinds have been employed without result. I now have to communicate the grievous results of a series of tentative experiments made by myself.

M. Lutz, the learned pharmaceutist of the Hospital of St. Louis, proposed the application of a solution of chlor-hydrate of aniline in these inveterate cases. I knew that there had been accidents among the workers in aniline colors, but they had always been attributed to the presence of arsenious acid; nor was I then acquainted with the very interesting articles by M. Beaugrand on poisoning by aniline; but, being assured of its safety by M. Lutz, who had lived for some months in an atmosphere saturated with the vapors of aniline without inconvenience, I did not hesitate to make the essay.

The first application was made on a man æt. 49, very intelligent, who had suffered for thirty-two years with an inveterate psoriasis, which had resisted all treatment both internal and external. He also had pulmonary emphysema, with asthma. The veins of the thoracic walls were largely dilated,—for which we could discover no cause, after a careful examination of the viscera of this region.

April 6.—At half-past six in the evening, a compress containing about 50 grammes of a solution, one-tenth of which was chlor-hydrate of aniline, was applied to the left arm. In an hour and a half after, vomiting occurred, which was repeated from fifteen to twenty times during the night. No diarrhœa; incontinence of urine,

the desire very urgent, slight smarting; very agitated during the night; cold, and icterode.

On the morning, 7th, the color cyanosed, face violet, and the eruption more distinct. Pulse 116, very small, but regular. Some râles in the chest. Pain very severe in the heels and calves. No cramps. Intelligence intact.

On the 8th the normal color is restored, and no trouble remains except pain in the heels. The patient now suffered from an indigestion, beginning after the use of this drug. On the 10th, at the request of the patient, an application of the drug (1 to 20 solvent) was made to the left knee, in order that the absorption might not interfere with respiration. In two hours cephalalgia, deep sleep, chilliness, labored respiration. No nausea, vomiting, nor trouble in micturition. Urine deeply colored, as in the first application. Cyanosis very pronounced. Voice lost.

The following day he had entirely recovered. Thinking these peculiar phenomena might depend on the idiosyncrasy of this individual, or on extreme susceptibility on account of the chest-complication, we made another essay on a patient who had witnessed the preceding experiment and who volunteered himself as a subject.

This patient, a vigorous old man, æt. 68, well preserved and intelligent, had been troubled with an inveterate psoriasis for twenty years, and had been treated by some of the most eminent surgeons of France.

June 6.—The first application of the drug (1 to 500 solvent) was made to the eruption on the right thigh, without appreciable result. The next day an application of 100 grammes of a solution (1 to 50 solvent) was made to the same place. Four hours after, he all at once lost consciousness, and became violet, as if asphyxiated; yet the respiratory movements were free. At the end of a quarter of an hour he recovered himself, though the cyanosis remained for four or five hours, and this gave place to a decided pallor, with abundant cold sweats. Insomnia during the following night. Urine very red. No fever, no vomiting,—differing from the other. Recovered next day.

In the analysis of the foregoing we deduce the following: that, though the structure of the skin is so decidedly altered, yet its power of absorption is little if any impaired, as we see symptoms of grave poisoning in less than two hours; that chlor-hydrate of aniline in medium doses may be a dangerous poison.

It impairs the oxygenation of the blood. The cyanotic appearance simulates that of subjects under the influence of protoxide of azote.

Another analogy between these two agents is the fugacity of the toxic phenomena.

Some essays have been made by Turnbull in the treatment of chorea by the sulphate of aniline, which have been followed by success. But Drs. Fraser and Daves, of London, and M. Bergeron have been less happy with their cases.

ON THE DIAGNOSTIC SIGNS OF FEBRILE DELIRIUM TREMENS.

Translated from *L'Abeille Médicale* of June 9, 1873,

BY JEAN PAUL BONSIEUR, M.D.

M. MAGNAN made a communication before the Société de Biologie on the diagnostic signs of the benign and grave form of inflammatory delirium tremens, and also to anticipate the grave accidents which accompany acute alcoholism.

The most important symptom is rise of temperature. In grave cases it rises from 38° to 39° (Cent.) on the first day, progressively ascending to 40°, 41°, 42°, and, in the height of extreme agony, will rise to 43°; on the contrary, in the cases terminating in cure, the course of the temperature presents on the first four or five days marked oscillations which show a prompt defervescence; when during the first few days the temperature keeps about 38°, the case is simple and cure certain.

The second sign is the shivering or muscular trembling which pressure on the muscles demonstrates; they are elicited, by percussion or strong pressure, from both the superficial and the deep muscles, and, what is more remarkable, can be produced during the sleep of the patient.

The third sign, less important, is a feebleness and paralysis which often amounts to a paraplegia of the lower extremities. The course of the temperature allows the greatest certainty in the differentiation between delirium tremens from an excess of alcohol, and that of wounded or sick, in whom the temperature is connected with the complications which follow in the course of their affection,—traumatism, pneumonia, erysipelas, etc. In idiopathic inflammatory delirium tremens the course of the temperature is characteristic. The pathological alterations in grave cases are hyperæmia of the gray substance of the cord, with miliary hemorrhages of the same.

The delirium, trembling, agitation, the appearance and heat of the skin, the acceleration of the pulse, afford very little information in this disease; whereas the study of the temperature and of the fibrillous contractions of the muscles affords a great precision both in prognosis and in diagnosis. The above statements are the result of numerous observations made by M. Magnan.

CHANGES IN THE SYMPATHETIC NERVOUS SYSTEM IN CONSTITUTIONAL SYPHILIS.—P. Petrow, of St. Petersburg, describes (*Virchow's Archives*, vol. xvii., March 1, 1873) the changes produced in the sympathetic nerve by syphilis, and arrives at the following conclusions. 1. The general disorder of the organism in syphilis manifests itself plainly in the sympathetic system by changes in the nerve-elements and in the interstitial connective tissue. 2. The nerve-cells undergo (independently of the interstitial changes) pigmentous and colloid degeneration,—more frequently the former. 3. The interstitial tissue partakes of the changes undergone by the same structure in other parts of the body, producing atrophy of the nerve-cells and fibres. 4. The endothelium which surrounds the nerve-cells in like manner partakes in the disease. At first there is increased size, with proliferation, of the cells; and afterwards fatty metamorphosis.—*Allgemeine Medicin. Central-Zeitung*, March 12.

A NEW USE FOR OLD STOCKINGS.—A plan of putting up simple fractures of the leg, which is not, we believe, generally known, and which country surgeons may sometimes find convenient, has lately been practised at University College Hospital. The broken limb is first bandaged with an ordinary roller; this is well coated with the gum and chalk mixture; a stocking is slipped on over this and similarly coated; another stocking is put on over this; and a final layer of gum and chalk over all. Thus, for a case of transverse fracture with little displacement, or of fracture of one bone, two or three stockings and a little starch or plaster of Paris supply a very neat and serviceable splint.—*British Medical Journal*, May, 1873.

CUTANEOUS ANÆSTHESIA (*Centralblatt f. d. Med. Wissensch.*, March 22, 1873).—Dr. Horvath, of Kiev, states that while water, ether, and mercury, at a temperature of —5° Centigrade, give intense pain before they produce cutaneous anæsthesia, alcohol and glycerin at the same temperature produce complete anæsthesia without any uncomfortable feelings.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 9, 1873.

EDITORIAL.

ECLECTIC STRATEGY.

MISERY makes strange bedfellows, says an old adage; but the wild riding of a hobby sometimes brings a man into even stranger and less desirable company than does misery. The Eden-like innocence and gullibility of men when approached through a violent and quixotic belief is a remarkable feature of human nature. Of all strange illustrations of these truisms the strangest is the sight recently exhibited of the old University of Edinburgh—the castellated home of conservatism, the royal mansion of learning, apparently inaccessible in its pride of an ancient race—sending out to the Far West, through the acts of its leading medical professor, not merely greetings, but words of cheer and encouragement, of praise and endorsement, sending them out not to a new school honestly striving for the spread of true science, but to an institution without repute among the regular profession,—one to bear whose insignia is to become a professional outcast. We do not enter into any discussion with the so-called "eclectics;" what they are and what they believe are as well known to our readers as to us; but certainly their name is, at least in this city, too closely associated with diploma-selling and other vile practices for them to be reckoned even with respectable homœopaths. Here, at least, eclecticism practically shelters men who are unable or unwilling to take an honest place and an honorable position in the regular profession, but resort to all sorts of methods to make money.

It is the sheerest folly for any body of men to claim to be a medical sect because they do not believe in the use of mercury, antimony, or arsenic. The regular profession enforces no therapeutic accord in its ranks. Any man is at liberty to use or eschew any remedy or set of remedies, according as his fancy dictates.

Professor Bennett is himself a striking proof of this. If it were otherwise, the profession would be broken up into almost as many cliques or divisions as there are drugs in the Pharmacopœia. The cry indulged in by the eclectics against these remedies is simply a battle-cry for plunder,—at least with many of them. It is to attract the multitude, to gain their confidence by agreeing with their prejudices, and thereby to get access to their pockets. In the West, eclecticism may have in its ranks honorable men. If this be so, we call upon them to come out from the others, and we say to them,—Whether you use this drug or that drug, so long as you yourselves allow individual freedom of opinion, so long as you yourselves are tolerant, so long will the regular profession fraternize with you. After all, however, we fear that in the West, as in the East, eclecticism means professional vagabondage; that its followers are the Bedouins, the Ishmaelites, of medicine.

It is into the hands of these gentry that Professor Bennett has fallen. Moved, probably, by letters of congratulation flattering to his pride of discovery and his intensity of belief, he has written the letter which we quote below from an editorial in *The Chicago Medical Times* of July, 1873, where it is headed "J. HUGHES BENNETT STILL IN THE ADVANCE:"

"DEAR SIR,—Your letter reached me here this morning, and I may say at once that I have not the slightest objection to the republication of my report of the Edinburgh Committee's researches on the action of mercury on the liver. I entirely agree with you as to the inutility or injurious character of mercury. As to antimony, I long supposed it served to dissolve the excess of fibrin in the blood, but find I do just as well without it. The influence of arsenic is very doubtful. I *never give it.* Indeed, it may be questioned how any chemical element which forms no part of the animal body can be of the slightest service in curing or relieving its morbid conditions.

"I was especially grieved to learn of the destruction of your college in the great fire of Chicago, but do not doubt that the well-known energy so characteristic of your countrymen will soon replace it on a secure and better footing. I shall be happy, so far as I am able, to contribute to its library a copy of all my works and separate published papers. * * *

"Yours very faithfully,

"J. HUGHES BENNETT.

"VICHY, FRANCE, May 23, 1873."

Because we respect Professor Bennett as an earnest, intelligent, original—although sometimes over-enthusiastic and illogical—student, because we honor the name of the institution which he represents, we are sorry that he has been so entrapped; though we do not wonder at it.

IN the present connection it seems fitting to say a few words about the celebrated researches of Professor Bennett in regard to the action of mercury upon the liver. On behalf of experimental medicine, we want to deny that these researches warrant the deductions which have been drawn from them, and which have not convinced the profession of their truth, but have brought experimental medicine into discredit with clinicians.

In the first place, it must always be borne in mind that there is a limit to be observed in reasoning from experiments.

No experiment is capable of overthrowing a well-known clinical fact. Thus, to quote examples, no experiment on animals could prove that opium is not a soporific, or elaterium a purgative, to man. We hold that every man can for himself on himself prove that calomel will produce an increase of bile in the passages, just as readily as he can that morphia will put him to sleep, and therefore deny that any experiments upon animals can prove the contrary.

In the second place, the effects of disturbing influences upon experimental results must always be borne in mind in reasoning from them. It has been stated by German investigators, and apparently proven, that mercury acts very differently upon dogs with biliary fistulæ than upon uninjured canines. When it is borne in mind that some believe that the calomel is absorbed through the agency of the bile, the significance of this fact is apparent.

Lastly, experiments always need repetition before their results can be accepted as experimental facts. In regard to Professor Bennett's experiments upon mercury, undue haste was, we think, generally shown in accepting them without this repetition, and it now seems most probable that their results were incorrect. Certainly, at the meeting of the *Gesellschaft der Aerzte* of the 28th of March, 1873, a paper was read by Professor Stricker, containing an account of some experiments he had made in conjunction with Dr. Rohrig on the circumstances influencing the secretion of bile, in which he asserted that the old methods of experiment were faulty, and suggested a new plan. He stated that on employing the latter method he had *found that calomel does increase the flow of bile in the dog.*

For these various reasons, we think that it is simply absurd to claim that it has been proved by the researches of Professor Bennett that mercury does not act on the liver.

THE lapse of centuries has not sufficed to surround the names of Cornelius Agrippa and Philippus Paracelsus with the customary halo of antiquity, nor have we yet learned to regard them as other than ignorant and impudent charlatans; but their fumigations, astrological tables, and "sympathetic powders" command a new respect, as at least harmless remedies, when contrasted with some of the blunders made by practitioners of medicine in this era of enlightenment.

An unfortunate lady, twenty-five years of age, being about to be married, and never having menstruated, consulted a physician. After making an examination *per vaginam*, he informed her that she had occlusion of that canal, and proceeded to make an incision through what he called an imperforate hymen. The resulting hemorrhage he declared to be due to the retained catameniæ. Painful micturition, dribbling of urine, and finally complete non-retention, followed this operation. After suffering for some time, she applied to another physician for relief. He attributed her difficulty to a condition which he designated as "closure of the urethra," and operated in his turn by dividing the anterior portion of the urethro-vaginal wall. After another long period of pain and misery, she fell into the hands of an educated practitioner, who found that her original condition was due to a congenital absence of the uterus, that the first operation had been through the wall of the bladder, leaving a vesico-vaginal fistula, and that the second had connected this fistula with the orifice of the urethra, laying open that canal along its entire length.

After having life made burdensome for six long years, she is at last on the road to recovery through skilful and judicious surgical treatment.

Our cotemporary who publishes this case, discreetly, and perhaps wisely, gives only the initials of the first two medical attendants; but it seems a shame that such monstrous and inexcusable ignorance cannot be exposed, so that it may at least be avoided.

A FEW weeks since, some laborers near the village of Dervock, County Antrim, Ireland, disinterred from a peat bog the remains of a woman in a curious state of preservation. The integument

was perfect, and was thoroughly tanned, but the bones had lost their solidity and were soft and compressible. The face, ears, tongue, and pharynx were undecomposed, as were the tendons, especially about the joints.

The body occupied a crouching position, about ten feet below the surface, and was five feet and one inch in length.

We have long been familiar with the preservative action of peat, which explains the condition of the soft parts in this case; but the disintegration of the osseous system is not so easily understood. It would seem possible that the presence of iron pyrites or some other oxidizable material might have furnished acid enough to dissolve the mineral constituents of the bones and leave the animal portion almost unaffected, as was found to be the case.

ON June 26 a formal presentation was made to Lady Paget of a beautiful portrait of Sir James Paget, painted in oil by Millais. It had been executed at the request of a large number of pupils, friends, and admirers, and was presented in the great hall of St. Bartholomew's Hospital, by Professor Humphrey, of Cambridge. In receiving the testimonial, Sir James referred with justifiable pride to the fact that there were in the audience three of his old pupils who are at the present time professors in the three most illustrious universities in Great Britain. In behalf of Lady Paget, he begged the governors of the hospital to accept the portrait, which will be hung with those of Abernethy, Earle, Lawrence, and Burrows.

WE are glad to learn that Dr. Sharpey, who has suffered from double cataract for fifteen years, has at last been operated upon successfully, is enjoying tolerably good vision, and has made his appearance again at University College, where it is to be hoped he will resume his valuable labors.

CORRESPONDENCE.

To the Editor of the Philadelphia Medical Times:

AS you have incorporated into your editorial upon cholera, of July 19, a lengthy extract from the report made by Dr. F. A. Ramsey to the mayor of Knoxville, relative to the outbreak of that disease in Greeneville, Tennessee, and as the contents of that extract are unreliable and untrue, I hope you will give the writer, who was a resident of Greeneville for twenty-four years previous to 1872, an opportunity to refute the foul aspersion cast upon the people of his native place, and to show that the cholera data deduced by Dr. Ramsey are more imaginary than real, and offer nothing as to the solution of the problem of the local causes bringing about so terrible an outbreak in a small town. When I read the above-mentioned extract in your editorial, I was perfectly thunder-struck that a man would so outrageously misstate facts and unhesitatingly throw out to the public such a malicious slander upon the good name and decency of the residents of a little village, and that, too, in a nonchalant, facetious way, which seemed to imply that the doctor delighted to ventilate the moral, ethical, and hygienic condition of a scourged people and to bring the reprobation of neighboring towns upon them.

Dr. Ramsey has never been a resident of Greeneville, and I have no knowledge of his having visited the place throughout the past eighteen or twenty years; and where he gathered material to make his report I cannot say. If it had come from Barnum, I would regard it as a huge joke; but emanating from a former editor of a Memphis medical journal, it assumes a more serious aspect.

Says Dr. Ramsey to the astonished mayor of Knoxville, relative to Greeneville, "More than a quarter of a century ago an *immense pit* [italics my own] was dug in the very centre of the town, and a cloaca erected over it with a capacity sufficient for the accommodation of the *entire community* during all these years." Strange and infatuated people of Greeneville, that you would all flock to a public privy behind a court-house, twenty feet long and ten feet wide, with only three apartments, making a pilgrimage several times a day to this unhallowed Mecca, according to Dr. Ramsey's statement, instead of enjoying the *priv*-acy of your own backyards! The fact is, Mr. Editor, for many years there has existed a public privy behind the court-house, for the accommodation of *country-people* coming to town to attend to business or to remain during the sitting of the circuit or superior court. The pit of aforesaid privy is about fifteen or twenty feet long, fifteen feet deep, and ten feet wide, and was dug *three years ago,—the old one having been filled up at that time.* This is the *immense* pit that haunted Dr. Ramsey's imagination, and which was for the accommodation of the "whole community." Verily, so overcome (!) am I at this point, the only further comment I can make is, Selah! Some Muse ought to strike the chords of his "heaven-resounding harp," and sing in melodious numbers of this *pit*-iful story, to commemorate a wonderful and lofty flight of the imagination! The energetic citizen of whom Dr. Ramsey speaks as a lineal descendant of Abraham did no more in emptying the contents of this "immense" pit upon his vineyard than many wise men have done and many still do; that art, according to my observation, is practised here in classic New England, where everything is supposed to be done upon scientific principles. Then follow more "vain imaginings:"

"It was the eastern side or slope of the hill on which

the deposit was made; and of course the wash was into and through the town. The heavy wash of this rain carried all the surface-soil from the hill; and, as the water *covered an area equal to three-fourths of the corporate extent of the town*, the débris from the pit, which it held, fairly divided, if not dissolved, was *distributed to just so much of the surface of the ground*" (italics my own). This proposition hasn't a living fact to support it, unless water is not subject to the laws of gravitation, and can run up hill as well as down. Water coming from that eastern slope *can only run one way after it gets to the bottom of the hill, and that through an open drain on the right side of Depot Street. This drain, as it nears Main Street, runs obliquely east, then southeast into a creek.* Therefore, as to this *débris* being distributed to three-fourths of the corporate extent of the town, which corporate extent is a mile in length by three-quarters in width, there is not a shadow of truth; and the doctor has been misled by somebody as ignorant of the topography of Greeneville as he is of the essential element of cholera itself. Why, sir, it would take a flood as big as Noah's was at the end of a fortnight to cover three-fourths of the area of the corporate limits of Greeneville, which abounds in hills and valleys throughout its whole extent.

One more flight of the imagination which we wish to follow, and then our criticism is ended. Here comes the "gem,"—a precious stone that never sparkled in any man's intellect during my residence in Greeneville, but perhaps during my absence of a year it has sprouted out, and the doctor has discovered it,—*i.e.*, that Greeneville people have found out the grape-vine liveth only through copious deposits of *human excrement* at the "root of each main stem." We quote verbatim et literatim: "But this is not all: the *pile* is yet incomplete! The town of Greeneville is a town of gardens, each garden-owner indulging an emulation as to who would have the best grapes. . . . *All the inhabitants of the town believed* that the *fæcal* deposit made by *men, women,* and *children* is of all things the best to give vigor to the grape-vine, fulness to the grape, and luscious delicateness to the flavor and mellowness to the odor of the juice of the fruit. Every cloaca in town," continues the doctor, "surrendered its contents, and at the root of each main stem was buried, in wet earth, a pile of human excrement." Here, again, I'm so astounded at the doctor's flattering compliments to the "men, women, and children" of Greeneville, that I'm compelled to pause and reflect upon the *frailty* of humanity. This proposition I believe to be not only an insult to every "man, woman, and child" in Greeneville, but untrue in every particular.

For twenty years *previous* to 1872 I never knew or heard of any citizen of the town making any such application to his grape-vines; nor do I believe that that custom has been in vogue *since* 1872. As for the "lusciousness, delicateness, flavor, and mellowness, etc., of the fruit," the doctor intermixes adjectives so with bad odors as to be really *fæces*-tious and funny. "Every cloaca in town surrendered its contents," *i.e.*, in Dr. Ramsey's *imagination, not in* Greeneville; and he couldn't convict the citizens of the place of such misdemeanor, if he even had Mark Twain's Virginia City jury to sit on the case. To come to plain truth, during my long residence in Greeneville I never in all my life saw or heard of a citizen emptying his privy-vaults as manure upon anything; and any man saying to the contrary is talking about something of which he is profoundly ignorant. How kind of a philanthropist to cast the foulest of aspersions upon the people of a little remote village, and, regardless of all truth and fairness, give forth such an opinion of "men, women, and children" as to lead the editor of this journal to say, "Greeneville was punished for the most reckless disregard of the first principles of sanitary science, if not of *common decency*."

Now, Mr. Editor, if Dr. Ramsey had with a ten-pound Parrott gun mounted that "eastern slope," and loaded it with human *excrement*, firing it off every ten minutes during the day, he couldn't more literally have befouled the town than he has in the extract you quote in your editorial; and if he should walk the streets of Greeneville and strike every "man, woman, and child" in the face with a handful of the contents of that "immense pit," (?) he couldn't insult them worse than he has by flinging his *fæcal* report to the general public. In considering the *unreliability* of the facts he put forth in his report, I conclude by saying that it invalidates any of his deductions as to the cause of cholera in Greeneville; and I hope to prevent any such report being placed upon the statistical tables of cholera; and, if space permitted, I could show that the cholera extended right in the *opposite direction* from the *excrementitious-washed* part of the town.

Very respectfully,
JAMES D. McGAUGHEY, M.D.

WALLINGFORD, CONN., July 21, 1873.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR:—One swallow doesn't make a summer; but the following result or coincidence astonished me, and seems worthy of record. I was called to see Mrs. S., aged 35, in labor with her ninth child. Very early in her seventh and eighth labors the womb had entirely given out, so that the child had to be delivered with forceps, although all the mother's parts were roomy and well relaxed. After the births severe flooding occurred.

At the time of my arrival, 12 midnight, there were some slight pains. At 3 A.M. the bag of waters broke; the os being soft, relaxed, and about an inch and a half in diameter. The pains shortly died entirely away, and at 4.55 A.M. the os was exactly as it had been at 3 A.M. I now exhibited four grains of quinine, and at 5.6, six grains more, all in solution. Shortly after the last dose she began to have cutting, grinding pains of some severity; but, having made up my mind that, as on the previous occasions, delivery with the forceps would be required, I was sitting in the next room, when at 6 A.M.

I was startled by the cry, "Come, quick! it's coming!" And, sure enough, on entering the room I found the head protruding from the vulva. It seems that there had been two sudden, long, hard, expulsive pains, which had completed the labor. The womb continued to contract; a female child of good size was soon born. The womb immediately became a "cannon-ball;" no blood was lost, and all went "merry as a marriage bell."

Yours,

OBSTETRICIAN.

PHILADELPHIA, July 26, 1873.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held April 23, 1873, at 8 o'clock P.M.,

Dr. W. B. ATKINSON, PRESIDENT, in the chair,

Dr. H. LEAMAN presented a pathological specimen of an *appendix cæci*, showing gangrene to the extent of an inch in its lower portion, in which there was a minute perforation. The appendix was of the usual length, presenting a patulous orifice on the cæcal surface, and lodged in its cul-de-sac a date-seed, which had separated into two parts. The gangrene and perforation were close to the seed, and between the seed and the inlet of the appendix.

The patient, a boy 14 years of age, was taken sick April 9, 1873, with sickness of the stomach, and vomited his dinner. When the doctor saw him, the next day, there was a resonant tumor in the right iliac fossa, with general abdominal tenderness. The constitutional symptoms were slight, and the patient anæmic. He died Sunday, April 13, 1873.

The post-mortem, sixteen hours after, showed, in addition to the above, a film of pus over the general peritoneal surface, with an accumulation of pus around the cæcum.

Dr. A. D. HALL said that a few years ago he had gone to the trouble of looking up these cases, and had accumulated fifty-eight or fifty-nine similar to the one just mentioned.

Dr. R. BURNS remarked that he was reminded of a somewhat similar case in his practice in 1851. The subject was a girl about 7 years of age. In the fall of that year she had dysentery, with much pain and great emaciation, which continued several weeks and resisted every means used for her relief. Acute enteritis was evidently manifest, which resulted in death.

On the 30th of November, 1851, a post-mortem examination was made, when a penetrating ulcer was discovered at the ileo-cæcal valve, in which was found a large grape-seed, which doubtless was the chief cause of the child's suffering and death.

Dr. BURNS said he believed many children perished by such causes, when their cases seemed to be mysterious and unaccountable.

Dr. J. S. ESHLEMAN referred to a case of inflammation of the cæcum, occurring in the person of his brother-in-law. Two years before his death he swallowed a piece of oyster-shell. During those two years he had occasional suffering and trouble. He died from an inflammation which lasted forty-eight hours. The piece of oyster-shell was removed from the ileo-cæcal valve, and the bowel was found thickened to the extent of three-fourths of an inch, but perforation had finally taken place. The doctor spoke of the propriety of removing the foreign substance in such cases.

Dr. H. Y. EVANS stated that he had seen cases of ulceration and dilatation of the appendix, yet in none of them had this abnormal condition been the cause of death. He had within a few days been present at a post-mortem in which the appendix was quite thin from fæcal distention, and he had no doubt that inflammation of the bowels occasionally has its origin in this vermicular process.

Dr. F. J. BUCK remarked that he had been using, for several years, at the suggestion of Dr. A. Nebinger, the sulphite of soda in the treatment of erysipelas. He was thoroughly impressed with the value of this agent, used internally and externally, both in the form of the sulphite and bisulphite.

Dr. L. TURNBULL had employed the sulphite and bisulphite of soda in "purpura." He was aware that it was a disease of debility, and in the treatment he had resorted to the use of good diet, tonics, such as the mineral acids, quinine, and iron, with acidulous drinks. Yet all these means failed to relieve his patients of the swelling and sanguineous patches of various sizes from the ankle to the knee. He then used these preparations of soda, administering teaspoonful doses, diluted in water, every three hours, and found the most happy results to follow. The pain and swelling disappeared, and the skin assumed its natural color, etc. He had used this remedy with perfect success in several cases.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JUNE 26, 1873.

THE PRESIDENT, DR. J. H. HUTCHINSON, in the chair.

DR. O. H. ALLIS presented a specimen of *popliteal aneurism*, which is the subject of an original communication in No. 92 of the *Medical Times*.

Dr. JAMES TYSON exhibited a specimen of *occlusion of the common bile-duct*, with apparent disappearance of the gall-bladder proper, its contents mingled with blood being contained in a cavity in the substance of the liver. (See a clinical lecture in No. 88, July 5, of the *Medical Times*, where the post-mortem appearances are also described.)

Dr. J. EWING MEARS presented portions taken from a specimen of *tumor of the right ovary* removed by Dr. Washington L. Atlee from a patient æt. 32. The growth from which the portions exhibited were taken was chiefly interesting owing to the fact that in it were presented two morbid structures, which were connected, though not related,—one of a benign, the other of a malignant character. The former consisted of a cyst containing a large quantity of fluid, whilst the latter was a large solid mass, projecting into, and, as it were, forming part of the wall of, the cyst; the greater portion of the mass, however, was exterior to the cyst.

The wall of the cyst was very dense, requiring some force to penetrate it with the trocar. The lining membrane was smooth, and did not differ in any respect from that of simple unilocular cysts. The fluid by microscopic examination presented the usual characters of the fluid of simple ovarian cysts.

On section and examination of the solid mass, it was found to be malignant in character, of the alveolar or colloid variety of cancer.

In remarking upon this specimen, Dr. MEARS alluded to the difficulties which presented themselves in determining, prior to operation, the nature of the morbid growth; more especially in reference to its benign or malignant character. The solid portion of the tumor

was firmly lodged in the pelvic cavity, and was in very intimate relation with the uterus, rendering it quite difficult to decide that it was not in some way connected with that organ.

Palpation and percussion determined very positively that the abdominal cavity was occupied by a cyst containing fluid. Tapping was performed, and a specimen of the fluid was submitted to careful examination. It did not vary from that usually found in simple ovarian cysts, either in its microscopical or chemical characters. The microscope did not show in the fluid any cell-structures which would have determined its origin from a cancerous growth. On a previous occasion Dr. MEARS had been able to diagnosticate the malignant nature of the tumor of the ovary by microscopic examination of the fluid contents removed by tapping, as was proved by post-mortem examination.

In this case, as clearly seen after the operation, the distinct separation between the two portions of the tumor prevented the discovery of its nature by examination of the fluid.

A diagnosis of multilocular tumor of the ovary (non-malignant) was, therefore, very naturally made. Another interesting question was suggested in discussing this specimen, relating to the priority of the morbid growths: whether, in this case, the ovary was primarily occupied by the cystic growth and subsequently became the seat of cancer, or the reverse. The history of the case is that of rapid development, covering a period of about nine months. The appearance of the tumor seems to indicate that the cancerous portion was developed subsequent to the cystic growth.

REVIEWS AND BOOK NOTICES.

SKIN DISEASES: THEIR DESCRIPTION, PATHOLOGY, DIAGNOSIS, AND TREATMENT. By TILBURY FOX, M.D. Lond. Second American, from the Third London Edition, re-written and enlarged, with a Cutaneous Pharmacopœia, a Glossarial Index, and sixty-seven additional Illustrations. New York, William Wood & Co., 1873.

The third edition of Dr. Fox's work upon diseases of the skin appeared in London a few months ago, and already, through the zeal of Dr. Henry, of New York, we are so fortunate as to possess another American edition, which reflects credit alike upon editor and publisher. The book is very well known, and since the publication of the first American edition has been extensively employed in our universities as a student's manual; but with the present edition its popularity must greatly increase, many marked improvements and changes being everywhere visible. The volume has been enlarged, and in parts so altered that the original is scarcely recognizable amid the quantity of new material to be found upon every page. We notice many of the chapters entirely re-written as well as re-arranged. Large numbers of illustrations have been introduced, borrowed almost exclusively from the publications of the German investigators, to whom modern dermatology is so much indebted for awakening an interest in pathological research. It must be gratifying to students of all nationalities to observe the friendly and generous spirit with which Dr. Fox has made use of and brought forward the studies which have of late appeared in both this and the Old World. This liberal kindly feeling for the true student, of whatsoever country he may be, is manifest throughout the entire work, and shows plainly the broad views which our author has adopted.

The present edition is nearly double the size of the former, and contains much new and original matter. Pathology is accorded a prominent position in the consideration of each disease, the author not only giving his own views, but also those of other writers. The description of the diseases is given in an easy colloquial style, without attempt at routine or formality; more condensation, perhaps, would have rendered the volume more acceptable as a scientific work. We observe also that many of the chapters have evidently been written in great haste; this is particularly noticeable towards the end, where certain diseases scarcely receive sufficient space. The book, however, taken as a whole, is an eminently good one, and well deserves the high position which it holds. We cheerfully recommend it as being the best work upon diseases of the skin which Great Britain has yet produced, and we wish it the success which it merits.

ACCOMMODATION AND REFRACTION. A Review of Dr. Fenner's Pamphlet. By DUDLEY P. REYNOLDS, M.D. Reprinted from the *American Practitioner* for July, 1873.

This pamphlet is another example of misspent time and labor. Its intention is to point out some glaring errors in a treatise on "Accommodation and Refraction," by Dr. Fenner; and in following out this idea the critic has held up to ridicule some slight misstatements which do not deserve the extended notice he has given them.

It is to be hoped that in the future a similar amount of energy will be displayed in a more worthy cause.

GLEANINGS FROM OUR EXCHANGES.

TRAUMATIC RUPTURE OF THE TYMPANIC MEMBRANE (*British Medical Journal*, June 7, 1873).—Mr. W. B. Dalby reported ten cases of this accident. In six of them the wound healed, and, when no inflammation in the tympanic cavity followed, a few days sufficed for the perforation to close. In the other four cases the wound did not heal at all. When suppuration had been once established in the tympanic cavity the treatment pursued was the same as in cases where the perforation had been the result of disease, and consisted chiefly in the use of astringents. No treatment was adopted when the injury was not followed by inflammation of the tympanum. It was found that the injury to the nervous structure of the ear behind the tympanum caused the loss of hearing, rather than the injury to the membrane, and that the greatest loss of hearing followed those accidents in which the greatest force was used in producing the rupture.

DEATH UNDER METHYLENE ETHER.—On Saturday last a patient on whom Mr. Lawson Tait was just about to perform ovariotomy, at the Birmingham Hospital for Women, died suddenly after the administration of five drachms of methylene ether. The anæsthetic was given through a single fold of a towel by the resident medical officer, and nothing noteworthy was observed during its administration. The pulse suddenly stopped, the pupils became dilated, and the respiration subsequently ceased. All efforts at restoration were fruitless. Post-mortem examination did not reveal the cause of death, the heart and all the other organs, except the ovary, being quite healthy. During life a halenic murmur at the base had been detected.—*London Lancet.*

NATURE OF MUMPS.—In a note on the above, read to the Academy of Sciences by Claude Bernard, the author, Dr. Bouchut, states that parotitis is simply a salivary retention due to catarrhal inflammation of the excreting canal of the parotid.—*London Lancet.*

PARALYSIS OF THE RADIAL NERVE CONSEQUENT ON EXPOSURE TO COLD.—At a recent meeting of the Société de Biologie, at Paris, M. Vulpian brought forward an interesting case of paralysis of the extensors of the forearm. In the month of January last, a man, aged 43 years, slept in a very cold and damp room, and awoke with a sense of chill, numbness, and tingling in the right hand and forearm, attended with complete loss of power over the extensors of the wrist and fingers. He was perfectly sober, and had lain on his right side, with the right arm outside the bed, naked and pronated, and with his head resting on the external part of the arm. The muscles reacted energetically to direct faradization, which was employed for six weeks without any benefit. It was then perceived that direct electrization of the *radial nerve* had no effect on the extensors of the hand and fingers, and when the electric treatment was applied directly to the nerve the patient speedily recovered. M. Vulpian thinks it probable that the paralysis in this case was due to the action of cold on the points where the motor-nerve fibres enter into an intimate connection with the primitive fasciculi of the extensor muscles of the hand and fingers. If this be so, the case would be somewhat analogous to what obtains in animals deeply curarized. In them, as we know from C. Bernard's experiments, the motor nerves preserve their excitability, and the muscles their contractility, and yet electrization of the motor nerves produces no contraction in the muscles supplied by these nerves.—*La Tribune Médicale*, 27th April, 1873.

NIGHT-SWEATS OF PHTHISIS.—In some valuable notes of practice in the Bellevue Hospital, New York, published in the *Medical Record* of that city, we find that for the relief of the above exceedingly troublesome symptom some patients are taking $\frac{1}{60}$ of a grain of sulphate of atropia in solution *ter in die;* some are taking $\frac{1}{100}$ of a grain at bedtime, and the success of this mode of treatment has already been sufficient to entitle it to further trial. Another plan of treating these night-sweats is also practised. It consists in taking the patient out of bed, if found sweating profusely in the night, sponging him with water as hot as he can comfortably bear, and, after being wiped dry and having his flannels replaced, putting him back to bed. It is stated that sometimes a single sponging will arrest the sweating for two or three days. In the French hospitals, according to a recently published thesis of M. Finot (*Rev. des Sciences Méd.*), agaric, tincture of aconite, phosphate of lime, etc., are employed for the same purpose. The reporter in the latter periodical, M. Rabuteau, speaks highly of the efficacy of phosphate of lime.

GENERAL USES OF DIRECT AND INDUCED CURRENTS (*Irish Hospital Gazette*, July 1, 1873).—Walter G. Smith, M.D., in a lecture on the Clinical Uses of Electricity, thus tabulates the therapeutic distinctions between the two forms of current:

DIRECT.	INDUCED.
To excite the nerves of special sense.	To stimulate the cutaneous nerves.
To reduce muscular spasm directly.	To antagonize muscular spasm by exciting the opposing muscles.
To produce chemical and thermal changes, *e.g.*, coagulation of blood, electrolysis, cautery.	
To stimulate muscles in certain cases.	To stimulate muscles in the majority of cases, and generally to obtain energetic peripheral excitation.
To relieve neuralgic conditions.	
To affect the brain and spinal cord directly, especially the latter.	

AMYKOSASEPTIN: AN ANTISEPTIC.—Amykosaseptin, or amycetoseptin, is an antiseptic consisting of a solution of borax combined with decoction of cloves. The author of a paper in *Allg. Med. Cent. Zeit.*, No. 46, 1873, thus describes its action: 1. Boric acid prevents bacteria from penetrating into the tissues, and thus prevents rot. 2. It destroys bacteria which may already exist in the tissues, and thus arrests rot. 3. It speedily kills true infusoria. 4. It is often a deadly poison for articulated animals and their larvæ. 5. It does not prevent the development of mildew. 6. The decoction of cloves only possesses in a limited degree the property of preventing the development of mildew, but it certainly delays the process and renders it difficult.—*London Lancet.*

ANTI-NEURALGIC SNUFF.—The *Rivista Clinica di Bologna* mentions an anti-neuralgic snuff prescribed with success in cases of facial neuralgia, by Dr. Scriffignano. The base of the snuff is quinine, and its composition as follows: Citrate of quinine, ten grains, very strong; exciting snuff (tobacco), fifteen grains. The medicament is said to act almost directly on the diseased nerve through the ethmoidal thread of the nasal ramus of Willis's ophthalmic, a branch of the fifth pair.—*London Lancet.*

CYSTOTOMY FOR SPASM OF THE NECK OF THE BLADDER.—Dr. Francesco Parona (Novara) reports in full in the *Rivista Clinica di Bologna* (May 10, 1873) two cases of spasm of the neck of the bladder cured by cystotomy, with the following conclusions: 1. The most certain means to cure this affection is incision of the neck of the bladder. 2. The operation of cystotomy is preferable to intra-urethral section.—*The Clinic.*

MISCELLANY.

A NEW poison has lately been discovered, called *inœa*, which is said to be more subtle than digitaline. It is obtained, by pressure, from the seeds of *Strophanthus hispidus*, an apocynaceous plant, found in Gaboon; and from experiments made with samples of it, taken from arrows, upon which the natives place it, it appears to act more powerfully than even digitaline, and quickly paralyzes the heart. Three milligrammes kill a frog, a sparrow, or a dog; though the resistance of certain animals varies. A snail, for instance, requires five milligrammes; a mouse has withstood three milligrammes of the extract (obtained by macerating the seeds in alcohol), while this latter dose kills a dog nearly a thousand times heavier than the mouse. The heart comes to a complete stand-still after a few irregular efforts.—*New York Medical Review.*

PROGRESS IN MICHIGAN.—Miss Dr. Frances A. Rutherford is Fourth Vice-President of the Michigan State Medical Society. She attended the recent session of the State Medical Society at Saginaw City. It is believed that this is the first instance of a woman's holding such a position in such a society in this country. Miss Rutherford is a graduate of a Philadelphia Medical College.—*Medical and Surgical Reporter.*

FROM Lord Bacon downwards, statesmen have frequently sought in scientific research a solace from the cares of office. M. Thiers is the last case in point. Deep in the Darwinian hypothesis, he is engaged on a work respecting the origin of the human species.—*London Lancet.*

Mr. F. A. Burr, editor of the Pottsville *Daily Standard*, writes as follows concerning the notorious Wharton trials:

"Reviving a Dead Issue.

"The circumstances preceding and attending the trials of Mrs. Wharton, in Annapolis, Maryland, for the alleged poisoning of General Ketchum and an attempt on the life of Eugene Van Ness, of Baltimore, are of such a nature as to lead one to suppose that, after the result of the trials, the whole matter would be allowed to rest in peaceful and proper oblivion. As the trials, the first at least, have attained the dignity of *causes célèbres*, we might naturally expect to find them made the fruitful source of parallels and precedents, by lawyers engaged in kindred cases; but that the medical fraternity, especially the experts who appeared for the prosecution, should continue to agitate the equivocal part there played by learned doctors, is singular, and not at all to their credit or reputation.

"In the beginning of the persecution levelled by the Baltimore college against Mrs. Wharton, there was very evidently more a feeling of professional pique, inciting the three leading medical witnesses for the State, than a desire for equal and exact justice. The most remarkable hesitation and shifting marked the determinations of the wise men who were experimenting on the body of General Ketchum; we say experimenting, for there did not appear a single evidence that intelligence had any part in the post-mortem examination. The symptoms which marked his illness and the circumstances attending his death were neglected, and a regular hunt after one hypothetical poison and another took place, the settlement being finally made on tartar emetic. Professor Aiken, the ancient chemist who conducted the first analysis, having arrived at a certain conclusion, whether rightfully or erroneously matters not, it seems as though his colleagues in the faculty of the medical college felt bound to endorse him, and by pen and voice, in court and out of court, by means of pamphlets, through the public press and by private channels, they strove to at once prejudice the public and shape even the verdict the jury was to render. At the time of the trial of Mrs. Wharton, being then in the service of the New York *Herald*, we made several direct and damaging charges against Drs. Chew and Williams, associated with Professor Aiken for the prosecution, which neither they nor their friends have had the temerity to deny, concerning this illegal and unprofessional conduct of everything connected with the autopsy, charges that, being acknowledged as true, would invalidate in law the most correct deductions of science and exclude them from evidence. In the immediate vicinity of Baltimore it is well understood that the trials, which have reduced Mrs. Wharton from comparative affluence almost to penury, were incited by the physicians, kept alive through their endeavors, and only failed to stamp her as a modern Borgia through the falsity of the assumptions whereon their assertions were founded.

"The jury in the second trial disagreed; and the State, seeing the impossibility to convict on the character of the evidence at its command, entered a *nolle prosequi*, and the proceedings, as far as the law is concerned, ended. But the faculty of the college are not yet satisfied; the erudition of these sapient professors is on trial at the greater bar of public opinion; and, as they could not hang the woman to save themselves, they keep lugging the case forward, through the medical journals, with elaborate arguments and specious pleas, challenging the verdict of the jury and imputing all sorts of motives to the witnesses, expert especially, for the defence. Neither in law nor in reason is this just. What private quarrels the opposing doctors have are more properly ventilated in private, and should be discussed in the lecture-room rather than be made immortal by being printed. What right attaches to Dr. Chew or P. C. Williams, M.D., or any other man, to declare Mrs. Wharton guilty? An expression of a belief in her guilt is within the province and privilege of every one; but we think that defeated spite is exceeding the bounds of moderation and justice when it reviews, *ex parte*, the antecedents of the trials and determines upon verdicts which intelligent juries, after hearing both sides, refused to render. Let the matter rest. The representatives of the Baltimore College faculty came off with anything but flying colors, and they should be content that the overthrow of their Castle of Knowledge has not been so complete as to leave no stone upon another."

The Indian Medical Service has sustained a severe loss by the death of an indefatigable and conscientious surgeon. Dr. Colles, who was a Fellow of the Royal College of Surgeons of Ireland, and Doctor of Medicine of St. Andrews University, died on February 7, at Dinapore. He had been acting in the room of Dr. S. B. Partridge, as professor of descriptive anatomy in the Calcutta Medical College, and, with characteristic enthusiasm, had exerted himself to a degree beyond his strength. In his exhausted condition he contracted the seeds of enteric fever, which, rapidly developing in very malignant form, carried him off before it had reached its crisis. His death has caused deep and wide-spread sorrow.

Dr. M. H. Henry has been appointed by the Commissioners of Emigration, Surgeon-in-Chief of the State Emigrants' Hospital, Ward's Island, New York. Dr. Henry succeeds Dr. Carnochan, who has held this position for many years.

Professor D. Warren Brickell, formerly of the University of Louisiana, has been appointed one of the Professors of Obstetrics and Diseases of Women and Children, and Clinical Midwifery, in the Bellevue Hospital Medical College.

To Remove Bad Tastes.—The bitter taste of quinine, colocynth, aloes, quassia, and other bitter medicines, may almost instantly be removed by chewing a small piece of liquorice-root, says *La Tribune Médicale*.

Hereafter the returns of deaths will be published monthly, instead of weekly.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF DISLOCATION OF THE SHOULDER, OF SIX WEEKS' STANDING.

RUPTURE OF AXILLARY VEIN DURING ATTEMPTS AT REDUCTION—RECOVERY.

BY PROF. D. HAYES AGNEW, M.D.,
Clinical Lecturer at the University of Pennsylvania.
With Notes by De Forest Willard, M.D.

GENTLEMEN,—I bring before you this morning a woman, 60 years of age, who states that she received an injury upon her right shoulder six weeks ago, and that she has since been incapable of using her arm.

The diagnosis, upon inspection, is not difficult. The shoulder is flattened upon its external aspect; my fingers can be easily hooked beneath the acromion process; there is a round hard prominence in the axilla; the elbow is carried off from the side of the body, and cannot be brought in contact with it without pain; the arm is lengthened; and the hand of the injured side cannot be placed upon the sound shoulder while the elbow is held against the chest.

Such a combination of symptoms can only indicate that the head of the humerus has left its normal articulating cavity and taken a position high up in the axilla, thus constituting the subcoracoid form of these luxations.

The other varieties are the subglenoid, the subclavicular, and the subspinous. Let us study these during the etherization of the patient (Squibb's pure ether used). Their names are sufficiently expressive of their positions. In the subglenoid form, the head of the bone lies upon the under surface of the neck of the scapula, yet it does not merely passively lie there, but is firmly and spasmodically held by the stretched supra- and infra-spinati, subscapularis, coraco-brachialis, teres minor, and deltoid muscles. The long head of the biceps is sometimes torn across, and all of the muscles, having suffered laceration to a greater or less degree, are irritated and spasmodically contracted.

In the subcoracoid variety, the same muscles are put upon the stretch, although not subject to the severe tension of the former case. The capsular ligament is badly torn, and in some cases the coracoid process may be fractured. Almost all subglenoid luxations become subcoracoid after a few hours, by the contraction of the muscles. The subclavicular is exceedingly rare, and is easy of recognition.

The subspinous is the only backward form known, and is quite rare. (Boyer says that it cannot occur without fracture of outer lip of glenoid.—De F. W.) Should it occur, however, the supra-spinatus would still be put greatly upon the stretch by being wound around the edge of the spine of the scapula; but the infra-spinatus and teres minor, which are inserted with it upon the great tuberosity, having their points of attachment brought nearer to the points of origin, would be relaxed. The subscapularis would be greatly elongated, or perhaps torn across, the humerus being rotated inward, and the elbow carried against the body.

In reduction, these two latter varieties are easily converted into one of the preceding forms, by simply elevating the elbow alongside the head and prying out the head of the bone, or by making traction downward towards the axilla.

The great frequency of dislocations at the scapulo-humeral articulation, equalling if not exceeding those of all other joints of the body, may be easily explained by the shallowness of the glenoid fossa, the extensive and varied movements to which the arm is constantly subjected, and the many powerful muscles which are attached to the upper extremity of the humerus.

In attempting, therefore, a reduction of a dislocation of this bone, it is essential that the force be applied in such manner as to favor the relaxation of the elongated muscles and then to assist them in drawing the bone to its place. True, a luxation may sometimes be reduced by traction, either downward, outward, or upward; but the most rational methods are certainly those which act upon the above principles.

It is for this reason that I prefer the plan of White or La Mothe, modified as described by Dupuytren, since by carrying the arm upward alongside the head, the supra-spinatus muscle, which is the one elongated to the greatest degree, is thoroughly relaxed, especially if the great tuberosity be rotated outward. The practical steps of this manipulation will soon be shown you, and I have found it almost uniformly successful in reducible cases.

Should this fail, however, traction may be made downward, with the heel in the axilla, as in Cooper's method; or outward, as recommended by Malgaigne. Still unsuccessful, either from a closure of the rent in the capsular ligament, or in consequence of adhesions, further extension may be made by a fillet attached to the arm and given to assistants or attached to pulleys, the counter-extension and fixation of the scapula being accomplished by a broad band through which an opening has been made sufficient to admit the arm to the shoulder. The traction can now be made in the various directions as before, but all the movements must be made slowly, steadily, and gradually.

The plans devised for the reduction of difficult cases have been many, but the general principles are apparent, and would suggest themselves to the mind of any thinking surgeon. In cases of long standing, the reduction, which is usually easy in a recent case, becomes either difficult, dangerous, or impossible. When the means already mentioned fail, Jarvis's adjuster may be tried; but when great force in any form is applied, the risks correspondingly increase. Fractures or severe lacerations have frequently occurred, the axillary vessels having been torn upon several occasions. I have never witnessed this accident, but it is, as you can readily see, a source of much danger, and should be always borne in mind, and carefully avoided if possible; although

I regret to say that neither the violence of injury inflicted at the time of the accident, nor the amount of subsequent inflammation, yields us any guide for prognosis in these cases.

In the case before us, the bone has been displaced for six weeks, and various attempts at reduction have been made, yet she has never suffered from pain and swelling, and we will hope that the adhesions are slight. Of course we look for some difficulty after this lapse of time; yet you will remember how frequently cases of luxation of two or three months' duration present themselves at this clinic,—two such cases having been reduced last week, as you recall, both with comparative ease.

I now seize the arm, and gently rotate it little by little, in order to break up all the adhesions which may have occurred. They do not seem strong, and the head of the bone is movable. I next elevate the arm alongside the head, rotate the great tuberosity outward, and, making counter-extension by placing my foot upon the acromion, pull steadily, cautiously, and unremittingly upward, for nearly ten minutes, the object being to bring the head upon the margin of the glenoid; and then quickly perform the second manipulation by bringing the arm quickly down and across the breast, while an assistant places his fist in the axilla. This movement, so successful in recent cases, fails in this instance.

Let me again search for the obstacle, and remove it if possible. I again rotate the arm until the head of the bone seems freely movable, and then make traction directly outward from the body, the counter-traction being made by the hands of an assistant. Again I fail.

This is one of the cases in which subcutaneous division of the capsular ligament has been recommended; but I do not consider it a safe operation, nor is it satisfactorily successful in accomplishing the end desired. Much more force could easily be applied by means of towels and pulleys; but there is always great risk of tearing the vessels or nerves, and an arm was even entirely avulsed by Guérin. We may try these methods, however, with caution. Before doing so, however, I will attach a fillet to the arm, and make one more attempt by La Mothe's method, as before. I draw steadily and perseveringly for several minutes, while an assistant's hand is held in the axilla to guide the head of the bone towards its cavity. It seems to ride upon the rim of the glenoid, but will not enter, even though I now bring down the arm over his closed fist. The case is certainly a stubborn one; but we will try another method.

NOTES BY DE FOREST WILLARD.

Just at this moment, a sudden and rapidly forming swelling appeared over the right pectoral region, distending in an instant the entire right breast, rendering it exceedingly prominent, and forming a firm but fluctuating tumor.

Simultaneously appeared the most alarming symptoms of marked alteration in the circulation. The patient instantly became cold, clammy, and collapsed; respiration ceased, the eyelids were half closed, and the heart's action was barely perceptible over the apex, and not at all at the radials. Professor Agnew's thumb at once compressed the subclavian artery, while the tongue was drawn forward by a tenaculum, and cold douches, ammonia, artificial respiration, etc., instantly tried. At first it seemed that the patient would die in a condition of fatal syncope; but by the opportune presence of a strong electric battery the current was quickly passed along the phrenic nerves, and in a few moments feeble respiratory efforts became visible. The application was continued for fifteen minutes, at the end of which time the patient had rallied so that the pulse was plainly perceptible at the wrist, and the surface commenced to show signs of warmth and life.

Preparation had meanwhile been made to ligate the subclavian, but upon removing the pressure it was found that the pulse could be felt at the wrist with a force equal to that of the other side, that the tumor was not tense and distended, and that it did not pulsate, neither did it seem to be filling with any rapidity or force.

The conclusion was therefore educed that the axillary or some other large vein had been ruptured, rather than the artery. No small vessels could have yielded so large and rapid a hemorrhage. Firm compresses were therefore applied over the swelling, and confined by a broad bandage, while pressure was kept up for two hours upon the subclavian artery in order to lessen the supply of blood coursing through the arm.

Meanwhile, stimulants were freely administered and artificial heat constantly applied to the extremities, and in three hours reaction was established to such extent that the patient seemed out of immediate danger.

The swelling which was accurately defined by the pectoral fascia extended slowly backward, but did not increase in tenseness. The patient passed a comfortable night, complaining, however, of stinging pains in the arm and breast, but with no further symptoms of depression. From this time onward her improvement was rapid, the pain and swelling gradually subsiding, and in ten days she was discharged from the ward. The blood gravitating downward and backward below the fascia finally made its appearance beneath the skin, where it remained until it was absorbed, weeks afterwards. Compression was continued for several weeks, followed by stimulating liniments; and now, ten weeks afterwards, having declined any further attempts at reduction, she has an arm which, although stiff and somewhat painful, seems to be forming for itself a new articulating cavity upon the inferior costa of the scapula.

In searching for other instances of this unpleasant accident, I find but one case in which a rupture simply of the axillary vein is recorded; and the cases of laceration of the artery are also quite rare. After a somewhat extended search through the reports of the hospitals of America and England, and in the various journals published in these countries, I have succeeded in collecting the following cases. The most complete records have been found in Malgaigne's Traité des Fractures et des Luxations, and in Flaubert's Mémoires sur plusieurs Cas de

Luxations, etc., Répertoire d'Anatomie et de Physiologie, 1827, and Hamilton's Treatise on Fractures and Dislocations, 1871.

The sole case of laceration of the axillary vein alone is that mentioned by Froriep,*—a scrofulous woman, æt. 36, in whom the dislocation had existed for twenty days. The vein was torn entirely across, and the patient died in one and a half hours.

This, and the one of Agnew's above recorded, constitute the entire list of accidents to the vein alone.

Platner† has put on record a case in which both vein and artery were injured, the patient dying of hemorrhage from the subsequent rupture of the sac.

Guérin‡ tore the entire arm from the body of a woman 63 years of age, in reducing a luxation of three months' standing, and of course all the structure at the axilla must have been severed.

Charles Bell§ also reports that during the use of the ambe at the Newcastle Infirmary not only was the axillary artery ruptured, but also the surrounding structures to such an extent that immediate amputation became necessary. It is highly probable that the vein was also injured; but the report is incomplete, especially in the fact that the result is not stated.

In Leudet's‖ case, in Rouen, 1824, an enormous swelling appeared in the axilla, immediately after reduction, which, though imparting no pulsation to the fingers, could be seen with the eye to rise and fall with the contractions of the heart. Gangrene supervened in three days, and the patient died in ten, of hemorrhage. A post-mortem examination revealed the fact that the artery was torn across, the rim of the glenoid fractured, and the muscles lacerated.

In Johnson's Medico-Chirurgical Review¶ are recorded several cases from the French of Flaubert,** in which that author states that he himself saw four cases of injury to the axillary or brachial vessels or nerves, and believes either that he has been singularly unfortunate or that other surgeons have not been honest in their reports.

One of these cases was an axillary dislocation, attempts at the reduction of which were followed by an enormous swelling, syncope, and extreme prostration, the patient narrowly escaping. Another was a dislocation of the elbow, which was followed by a similar result, the brachial artery probably having been injured. Another was undoubtedly emphysematous, as the tumor appeared during violent outcries, and was supra-clavicular, extending over the shoulder and to the back; and in the remaining case the nerves were lacerated. He also reports another case in which the patient died after attempts at reduction of a dislocated hip.

Verduc†† ruptured the artery, and the patient died.

Petit* and Delpech† met with similar accidents and similar results.

David,‡ Hôtel de Rouen, reduced a luxation of several weeks' standing, using immense force, and the patient died of mortification, the supposed cause being a rupture of the artery.

Pelletan,§ while attempting to reduce a luxation of four months' standing, discovered a tumor which he supposed to be emphysematous, but upon opening it the patient perished from hemorrhage.

Dupuytren‖ reports a case in which a woman 60 years of age had an axillary dislocation of six weeks' standing successfully reduced. Two or three months subsequently, however, a tumor appeared in the axilla, which, being mistaken for an abscess, was opened, and the patient died on the eighth day from secondary hemorrhage.

Nélaton¶ also had an aneurismal tumor appear three months after the reduction of an axillary dislocation, for the cure of which he tied the subclavian, but with what result is not recorded.

Malgaigne** was compelled to desist from attempts to reduce a displaced humerus of sixty-eight days' duration on account of the occurrence of a tumor in the axilla, which being, however, subsequently arrested in its growth and absorbed under the use of ice, compression, etc., he decided to be due to rupture of the muscular branches instead of the axillary.

Desault†† met with two or more cases;‡‡ but they are to be received with some doubt, having been considered by him as "tumeurs aériennes," or instances of emphysema. Malgaigne, however, believes that they were produced by a rupture of at least the muscular branches of the artery, "the pulse of the patient being scarcely perceptible in the side affected and a syncope which supervened appearing to favor the suspicion of a rupture; but—in the absence of fluctuation, of pulsation, and of any change in the color of the skin—the return of the pulse, the circumscription of the tumor, its resistance, and the sound caused by striking upon it, produced the belief that it was owing not to an effusion of blood, but to a disengagement of air that had been confined in the now lacerated cells of the cellular membrane." The tumor entirely disappeared in thirteen days, leaving a large ecchymosis, however, for a month or more.

Callender§§ tore a small opening in the upper wall of the artery in attempting to reduce a dislocation of six weeks' standing. He very wisely laid open the tumor, turned out the clot, and tied the vessel both above and below the bleeding orifice. The patient died soon after with symptoms of pulmonary embolism.

Warren,* of Boston, reports a case in which a man 30 years of age fell and dislocated his shoulder. Violent attempts at reduction were made, and, according to the statement of the patient, the booted foot of the operator was placed in the axilla. When he entered the hospital, the arm and shoulder were greatly swollen, but after this subsided the bone was found in its normal place. Five days subsequently, during a fit of coughing, something "gave way," soon followed by a large swelling and discoloration in the axilla. No pulse could be discovered at the left wrist, and the tumor in the axilla became enormous. In six weeks an abscess formed and opened, discharging dark, coagulated blood. Upon the third day there was a sudden gush of blood, which was arrested by pressure, and on the following day Warren tied the subclavian artery. The patient made a good recovery, and in one year afterwards slight pulsations could be distinguished in the radial. In sixteen months the man was greatly improved.

Gibson† twice met with the accident, and was honest, as usual, in reporting each case. The first was in the person of a man 50 years of age, whose left shoulder had been dislocated for two months. For two weeks subsequent to the accident it had been treated as a fracture, and after this ineffectual attempts had been made to reduce the deformity. He was admitted to the Philadelphia Hospital, and, after various manipulations and the trial of all the ordinary means employed, success was at last attained, and the head of the bone slipped into its place. In a short time, however, a swelling was noticed in the axilla, which slowly increased in size, the patient being painless and cheerful, until the evening, when, the symptoms of depression becoming alarming, Professor Gibson was sent for, but arrived too late to save the patient.

At the autopsy the artery was found entirely torn across, it having been firmly bound down by old adhesions to the capsule of the joint where it surrounded the neck of the bone.

His second case was a man 35 years of age, who had dislocated his shoulder nine weeks previous to his entrance into the hospital, and who had already passed through four attempts at reduction, in one instance having been suspended by the axilla over a door.

After a week's depletion, in accordance with the practice in vogue at that time, the attempt was again made by Gibson, assisted by a number of prominent surgeons. Extension and counter-extension were maintained by pulleys for half an hour continuously, after which rotary movements and all the usual methods of reduction were faithfully but cautiously and gently tried for one and three-quarter hours, when they were finally successful.

Upon the next day, however, a pulsating tumor was discovered in the axilla, and on the following morning Gibson proceeded to tie the subclavian. The man, however, sank, and died on the eighth day.

At the post-mortem examination, which was carefully and accurately made, and which is fully described in his report of the case, the left hand and forearm were found in a state of incipient gangrene, while the ligation-wound showed no attempts at union.

The artery was firmly attached to the bone and articular capsule by a ligamentous substance so compact and with so short a portion of the artery between this point of adhesion and the false attachment to the rib that it could hardly have escaped injury. The ends were separated half an inch, the utmost limit allowed by the adhering bands. The external coat of the artery formed the sac of the aneurism; but this had ruptured and allowed the contents to escape into the connective tissue.

"The walls of the true aneurismal sac were of so compact a texture, and its boundaries so well defined, that the conjecture of its having existed previously to the reduction of the bone and that its rupture was a distant and subsequent event, is rendered probable."

The great tuberosity of the humerus had been fractured, but had partially united.

Blackman,‡ of Cincinnati, attempted the reduction of a dislocation of sixteen weeks' standing, which had previously resisted the efforts of six men with pulleys for two and a half hours. The manipulations of reduction, rotation, abduction, and elevation had been continued about ten minutes, when a sudden tumefaction occurred in the pectoral region and rapidly increased in size.

No pulse could be felt at the wrist; and, believing the artery to have been ruptured, the axillary was tied at the upper third of its course. Pressure was made by a broad band and compressed sponge, and on the following day the bulk was greatly diminished.

The patient did well for several days, but on the eleventh he perished from a hemorrhage at the seat of the ligature.

Lister§ recently attempted the reduction of a dislocated shoulder of eight weeks' standing. The displacement was of the subcoracoid variety; and while pulling upward, as in La Mothe's method, he heard a distinct crack. No swelling appearing, however, and the head of the bone being still in its false position, various manipulations were employed, and the pulleys used, traction being made both downward, outward, and upward. The force employed was not excessive, and efforts were finally discontinued.

Almost immediately afterwards, however, his attention was directed to an enormous swelling which appeared below and behind the axilla, almost as large as an adult human head. The pulse being absent at the radial of the injured side, a rupture of the axillary artery was diagnosed, and the operation of tying it commenced. An incision was made directly into the axilla, and the extravasated partially-coagulated blood turned out.

‡ Western Lancet, Nov. 1856.

§ Lancet, Feb. 1, 1873; Edinburgh Medical Journal, March, 1873.

The arm being held off from the side, the artery was so compressed against the head of the bone that no hemorrhage occurred; but upon being relaxed by the side of the body a free bleeding took place. The orifice was at last found to be concealed upon the posterior wall, from which a stream was so poured out into a cavity and reflected forward that it seemed to be a regurgitant stream from a large branch like the subclavian. Careful examination, however, proving that the main vessel was ruptured, a ligature was applied both above and below the opening, the vessel cut across, and the ends again secured. The opening was found to be about two lines in diameter.

The head of the bone was then removed, to facilitate subsequent reduction. The patient, although greatly reduced by the loss of blood, rallied a little, but soon sank, and died in three hours.

Mr. Lister, in his report of the case, regrets that he did not transfuse.

At the autopsy the explanation of the accident was evident, and is so instructive that I quote it in full:

"The surface upon which the head of the bone had rested in its new situation simulated cartilage in smoothness and firmness, and was formed anteriorly by a dense fibrous structure, strengthened with a considerable amount of osseous deposit in the form of a spicula, proceeding chiefly, though not exclusively, from the coracoid process and the surgical neck of the humerus: a state of things fully confirming the wife's report as to the long time that had elapsed since the accident. The broad and strong osteo-fibrous band thus connecting the humerus with the coracoid process had lain over the head of the bone, constituting a partial capsule for the new joint. At the same time it was intimately connected throughout, by condensed tissue, with the sheath of the axillary artery, which lay over it. Thus the vessel, instead of being surrounded by loose and yielding structures, as in the natural state, was attached, through the medium of the osteo-fibrous band, to the coracoid on the one hand and the neck of the humerus on the other; and when these bony points were separated from one another by the lever-like action of the humerus when the limb was drawn upwards, the artery as well as the band was necessarily subjected to violent traction. Accordingly, the band, as strong as it was, was found to have been torn right across, and the rent in it was exactly opposite to the rupture in the artery. The giving way of the vessel had been rendered the more easy by atheromatous degeneration of its walls, which was present in an advanced degree. The vein also showed evidence of having been extremely stretched, by considerable narrowing of its calibre at the same situation.

"The chief lesson to be learned from this sad case seems to me to be that in subcoracoid luxations there may be, as early as eight weeks after the accident, such adhesion of the artery to the scapula and the humerus as to make it dangerous to employ even the manipulative treatment without the pulleys, and especially the upward traction of the limb. For, as was remarked before, and will now be readily understood, the snap heard in the preliminary manipulation was in all probability caused by the rupture of the fibrous band above described, accompanied by the giving way of the vessel."

In common with Mr. Lister, Professor Agnew also believes that the method of reduction by traction upward is, in old dislocations, more liable to produce a laceration of the vessel; and although it has been his favorite mode, and will be continued in all recent cases, yet in those of long standing he will first attempt others which do not put the artery so greatly upon the stretch.

He also believes that the limitation of the circulation by controlling of the subclavian assisted greatly in keeping a sufficient supply of blood in the brain to prevent fatal syncope, and that in such sudden cases compression even of the abdominal aorta would be beneficial in keeping up the proper meningeal supply.

Another case, which would come very properly under a report of this kind, is recorded by Adams.*

The rupture of the artery in this case was not produced by the surgeon, but by the same accident which occasioned the luxation. The patient was thrown down by a runaway horse, and was brought to the Jervis Street Hospital with his left humerus dislocated and with an enormous swelling of the axilla. No pulse could be detected in the radial or brachial arteries of the injured side, and the patient was cold and prostrated, and so relaxed that the bone was slipped into its place by a slight manipulation.

The deep axillary swelling remained stationary for several days, no pulsation being perceptible either in it or in the arteries of the limb. After ten days, O'Reilly found the tumor upon the increase, and tied the subclavian in the third portion. The patient was seized with erysipelas and lost two fingers by gangrene, but he finally recovered, and was under observation several years afterwards.

The above constitute all the cases which have been discovered, and I believe that the report is complete to the present time.

Recapitulation.—Rupture of vein alone, 2 cases,—Froriep and Agnew: 1 fatal, 1 recovered.

Rupture of vein and artery, 3 cases,—Platner, Guérin, Bell: 2 fatal, 1 not stated.

Rupture of artery, 19 cases,—Leudet, Flaubert, Verduc, Petit, Delpech, David, Pelletan, Dupuytren, Nélaton, Malgaigne, Desault (2 cases), Callender, Warren, Gibson (2 cases), Blackman, Lister, and Adams: 12 cases fatal, 6 recovered, 1 not stated.

The axillary artery was tied in 3 cases,—Blackman, Callender, Lister: all fatal.

The subclavian was ligatured 4 times,—Gibson (fatal), Warren (successful), Adams (successful), and Nélaton (not stated).

(Gibson did *not* tie the subclavian in his first case, as reported in most of the Surgeries.)

Total, 24 cases: 15 terminated fatally, 2 are uncertain, and 7 recovered.

* Todd's Cycl. Anat. and Surg., art. on Shoulder, Abnormal Conditions of, p. 616; Holmes's Surgery, vol. ii. p. 827.

The successful cases were those of Desault (2), Flaubert, Malgaigne, Warren, Adams, and Agnew.

The case of Adams perhaps ought not to be reckoned with the others; yet it is so parallel an accident that I have deemed it advisable thus to place it.

Serious injury has also frequently been done to the axillary nerves; in some cases even the plexus being torn from the spinal column, in others various degrees of paralysis of the arm having followed. Malgaigne, Hamilton, Lenoir, Larrey,* and others report a number of cases.

Michaux (Hôpital de Louvain, 1841)† in reducing a luxation of the elbow tore off the median nerve and the brachial artery. He amputated, and saved his patient.

Various other accidents are reported as the results of efforts at reduction, but the above are all that are directly connected with the dislocation under discussion.

The cases are certainly sufficiently numerous to warn us against employing too much force; yet in the immediate case under notice only manual traction was made.

ORIGINAL COMMUNICATIONS.

YELLOW FEVER.

BY HARVEY L. BYRD, M.D.,

Professor of Diseases of Women and Children in the College of Physicians and Surgeons of Baltimore; President of the Epidemiological Association of Maryland, etc., etc.

Read before the Association by Appointment.

IN presenting yellow fever for the consideration of the Epidemiological Association, no attempt will be made at mere literary display, or the clothing of ideas and facts with the charms of rhetorical drapery. As all science is but nature understood, and she is when unadorned adorned the most, our subject will be treated in as simple and perspicuous language as practicable. It must, however, be obvious that within the limits of a brief paper like this only the outlines, so to speak, of a subject so voluminous can be drawn; and attention will therefore be directed chiefly to those facts and observations which have come more immediately under our personal notice, or have been gleaned with some care from the writings of physicians of large experience in treating the disease, as those most likely to afford any particularly attractive features to a scientific body like this.

HISTORY.

Nothing concerning the source or origin of yellow fever can be obtained from the various names by which it has been recognized or described. They relate either to the place of visitation or invasion, or to some fancied or real pathological change of most frequent occurrence during the prevalence of the disease in an epidemic form. It was probably first introduced into Southern Europe, the West India Islands, and the continent of North and South America, from the west coast of Africa, its natal place. Had European ambition for extended dominion and territory, or the avarice and cupidity of the New England slave-trader, never attempted the invasion of the jungles of Western Africa, there is reason to believe that the hecatombs which have marked the visitations of the pestilence in the West Indies and on the shores of this continent, at least, would never have been known. The autochthones or aborigines of those lands knew nothing of the disease until brought to them by ships engaged in a most unholy commerce. As it is chiefly with the disease as it concerns us of the United States we purpose to deal, it may be observed that the summer, or warm season of the year, is the period during which its visitations have prevailed epidemically and been most destructive in their character.

LOCALITY.

As it is comparatively unknown in the country, and confined almost exclusively to cities and large towns, as an epidemic, and as in those cities and towns holding commercial relations with tropical countries it always establishes itself before interior localities become affected, the importance of strict quarantine regulations in such commercial cities during the hot season cannot be overestimated. It might prove interesting, did time permit, to introduce the date of its visitation to the several cities of our country, and the duration and severity of the same; but we must pass on, merely mentioning a few of the principal cities in which it has prevailed, viz.: Boston, New York, Philadelphia, Baltimore, Norfolk, Wilmington, Charleston, Savannah, Mobile, New Orleans, and Galveston. It will be observed that all the places named are seaport cities, or cities engaged in foreign commerce. From Charleston and Savannah it has been carried when epidemic to Beaufort and Blackville, South Carolina, and to Augusta and Darien, Georgia; from Mobile to Selma and Montgomery, Alabama, and from New Orleans to Natchez and Vicksburg, on the Mississippi River, and other places of note, thus *proving* that it is a *transmissible* disease.

SEASON.

With a protracted temperature in our sea-board cities of from 85° to 93° Fahr., the introduction of the yellow-fever germ or fungus will as certainly develop that disease in the unacclimated Caucasian, as the introduction of the smallpox germ will give rise to that scourge in an unvaccinated community.

CAUSE.

From what has just been stated, it will be seen that we believe the disease to depend upon a *specific* cause, and that cause to consist of organic matter. This theory is sustained by a number of well-attested facts. Like much of the flora indigenous to hot climates, the yellow-fever germ or fungus requires for its proper development and growth a certain continuous temperature. Eighty-five to ninety or

* Bul. de la Soc. Chirurg., i. 1.
† Debruyn, Des Luxations du Coude, Thèse Inaug., Louvain, 1843, p. 77.

ninety-five degrees of Fahrenheit is the temperature which experience has shown to be most favorable to the spread of yellow fever epidemically in this country, and like exotic plants, when *exposed, the yellow-fever germ is effectually destroyed by frost.* In the West Indies, and in the tropical districts of this continent, where the summer temperature is perpetual, these germs have become naturalized, so to speak, and the disease is found to exist perennially in some cities, by the continuous introduction of the unacclimated.

The winters in all the sea-coast cities of this country, except possibly New Orleans and Galveston, are too cold for the yellow-fever germs or fungi to be perpetuated, and they must, therefore, be re-introduced from season to season in order to the production or development of the disease. It is a disease *sui generis*, as contagious under favorable circumstances as smallpox or hooping-cough. Assertions of this character are not made lightly, or without due consideration of their import and value. *It bears no striking resemblance to any other form of disease*, and when once carefully studied at the bedside, and in the dead-house, can *never be mistaken*, by an intelligent observer, *for any other affection.* When *the important test* is applied, that is recognized as of such *uniform value in other known forms of contagious disease*, it will be found to respond with *much greater* emphasis and distinctness in yellow fever *than in any other disease;* viz., *one well-defined attack of yellow fever protects* the survivor, *with almost absolute certainty*, from a subsequent one. On this question, Dr. Bartlett says,—

"This point in the natural history of yellow fever was made the subject of a special and formal investigation, after the cessation of the epidemic at Gibraltar in 1828. At the instance of Sir William Pym, a commission was appointed for the express purpose of collecting such facts as might settle the question. The commission consisted of thirteen physicians,—French, English, and Spanish. The medical men of Gibraltar, civil and military, thirty-three in number, all of whom had been familiar with the disease, appeared before the commission and stated the results of their experience. The aggregate number of patients with the disease, seen or treated by them all, amounted to about *twenty-seven thousand.* These physicians were invited to state the number of cases in which they had known the disease to occur a second time, and, as simple assertions were inadmissible, the commission decided that they would receive those cases only in which the symptoms of the first and second attacks could be given, whether these symptoms had been noted by the physicians who communicated them, or whether they came through the patient himself but were unequivocal. The whole number of cases of presumed double attack, thus communicated to the commission, was only *thirteen.* Upon these thirteen cases each member of the commission expressed his opinion by a vote, writing upon a piece of paper the word *evident, probable, doubtful*, or *inadmissible*, for each case. A majority of the commission declared in this manner *one* of the cases *evident*, three of them *probable*, and the remainder *doubtful* or *inadmissible.* The following fact, on a much smaller scale, but hardly less conclusive, was communicated to the commission by M. Broadfoot. The military domestics employed during the epidemic in the care of the sick were one hundred and sixty in number, and none of them had had yellow fever in any anterior epidemic. The civil domestics were sixty-one in number, and, with two exceptions, had already had the disease. These two, and these two only, among the last, contracted the fever, and forty of the military domestics, all the rest escaping. Other facts of a similar character were also presented to the commission. Slight and mild attacks of the disease seemed to be quite as preservative against its recurrence as grave and severe ones; and it did not appear that the protective effects were in any degree diminished by time."

RACE.

The *native* African is *exempt* from the disease as it has prevailed in this country, and even his descendants, for four or five generations, in our Southern cities, enjoy great immunity from it. In 1820, during a devastating epidemic in Savannah, Georgia, Dr. W. C. Daniel, a most enlightened and distinguished practitioner, who was personally known to us for several years before his death, stated that "near three hundred native Africans recently captured on the coast by government vessels were brought to Savannah, and remained there during the epidemic, and not one of them took yellow fever." We have never seen a case of *black vomit* in a genuine negro, however long his ancestors may have resided in the South. The most susceptible race is the Caucasian, and the purer the type the greater the liability to the contagion. The mulatto occupies, so far as susceptibility to the fever is concerned, an intermediate place between the Caucasian and African races, being less liable than the former and more exposed to an attack than the latter, his liability or exemption being dependent on the greater or less amount of Caucasian blood. Thus, the mulatto—half white and half negro—may be said to be half as liable to an attack on exposure to the contagion as the white man; the quadroon, one-fourth as much so; and the octoroon, or third remove from the white race, one-eighth. Are these statements of no significance? Extended observations have proven them facts.

SEX.

More males fall victims to yellow fever than females. Greater exposure to the weather, if it should have no other effect, predisposes the male sex more than the female to the epidemic influence. As a rule, the *strong* and *robust* at the commencement of an epidemic suffer more than those who, from feeble strength, are unable to take active part in business concerns.

ACCLIMATION.

As already stated, one attack almost certainly protects the individual from a subsequent one. Continuous residence for many years in yellow-fever regions produces a degree of exemption

which protects the individual from the disease in mild epidemics in many instances. But nothing affords surety to the white man in severe visitations save a previous attack of the disease.

MARSH MIASMA.

Observation shows that certain precedents are followed by certain subsequents. Both observation and experience prove that of all the laws by which events are linked together the relation of cause and effect is the most unvarying and the most constant; and we are led to believe that the laws which govern the development and motions of the heavenly bodies are not more unvarying in their operation than those which control the action and influence the development of the small and minute particles or atoms of matter existing in all parts of creation. Wherever matter exists, force resides, which latter can be brought into active operation under its own or appropriate stimuli.

To concede the government of the sun and the planets to the operation of certain and immutable laws which we know to be true, as calculations concerning them have been made with mathematical accuracy and precision, and to deny the existence and operation of equally certain and unchangeable laws in the development and treatment of disease, would be to rob Deity of half his attributes and perfections. While we admit that the same accuracy and precision in the present state of our knowledge are unattainable in our investigation of the causes of disease and the action of remedies, we are nevertheless not to conclude that order and symmetry, relation and harmony, do not exist in the microscopically small as well as in the great bodies of the universe, simply because the laws which govern them cannot now be presented with unerring accuracy and precision or clothed in the imposing array of mathematical formula. Contingency and verisimilitude are therefore but the legitimate offspring of human ignorance and superstition, and hence cannot be supposed to have any existence in an enlightened and cultivated intellect.

Miasma or *marsh effluvium*, the prolific source of intermittent and remittent or bilious fever so called, is *not* the source or cause of yellow fever. In certain districts and communities where bilious fever is an annual visitant, and where its appearance is looked forward to with the greatest dread and apprehension, yellow fever is totally unknown. Georgetown, S.C., situated in the midst of the rice-growing region of the Pedee and Waccamaw Rivers, has never suffered from a visitation of yellow fever, though on the coast and less than fifty miles from Charleston. Yet in this notoriously insalubrious climate, though bilious fever has scourged it more or less frequently since its early settlement, with a violence, it was said a few years ago, unsurpassed by any other town in the world except Alexandria in Egypt, never has a single case of yellow fever originated within its limits. It is known that yellow and bilious fevers may exist or run *pari passu* for a time in certain localities; and from this circumstance, doubtless, the idea of its miasmatic origin was conceived. This hypothesis is erroneous, as the two diseases differ as widely in their symptoms and pathological appearances as any other known diseases whatsoever. In fact, there is great paucity in the common phenomena of the two fevers, and no parallelism whatever can be drawn between the leading symptoms. They are *proven* separate and distinct in various ways; but only some of the more prominent evidences of this assertion need be introduced in this place. First, *marsh miasma* will produce intermittent and remittent fever alike in the white, copper-colored, and black races, when exposed to its action, and it will continue to do so from year to year so long as the parties reside in miasmatic localities, no point of acclimation or exemption being ever attained. Yellow fever, on the contrary, affects the Caucasian race chiefly, the African being almost wholly exempt in the Southern States, however much exposed. Again, one attack is almost absolute protection against a subsequent one, no matter to what extent the party may be exposed to the disease. More could be said on this point; but this must suffice.

A careful examination of many localities where yellow fever has prevailed proves them free from even the existence of marshes, and therefore from marsh miasma. Dr. Gillhurst says, in speaking of Gibraltar, "It cannot be admitted that Gibraltar furnishes sources from which *malaria, in the usual sense of that word*, arises sufficient to account for the appearance of a malignant fever." "The island of Barbadoes is described," says Dr. Bartlett, "as rocky and dry, with very little marshy or wet land. Brimstone Hill, in the island of St. Kitts, is a conical mound rising to the height of seven hundred feet above the level of the surrounding plain. It is described as a volcanic rock, dry, nearly destitute of vegetation, and desolate in its entire aspect. It is generally free from yellow fever, but not uniformly so. In 1811 and 1812 the disease appeared there, and was very fatal. Stony Hill, in Jamaica, is 1300 feet above the level of the sea. It is described as an entire mass of calcareous rock, covered with trees except on the summit, but with little soil, and producing scarcely any grass or plants; and yet yellow fever does sometimes prevail extensively among the troops stationed on its summit."

CONTAGION.

In the sense in which the term contagion is usually understood, yellow fever is a contagious disease. Some have objected to the term, even where the individuality of the disease is admitted, and say that it cannot be used to designate that mode of propagation which we recognize in smallpox, measles, etc. If what was said a while ago, when speaking of its *transmissibility*, and of the temperature in which the germs are found to develop and propagate most rapidly,—viz., prolonged heat of 85° to 90° Fahr.,—be borne in mind, it will be readily understood how the inhabitants of a city in which these germs have been introduced will sooner or later become impressed by them, and how strangers from healthy localities may contract the

disease when visiting an infected city even for a few hours, and sicken and die, or carry the germs of the fever to healthy communities. Instances under our own notice and the observation of intelligent physicians have so frequently occurred, and are so well known and understood by the non-professional even, in yellow-fever districts, that more than mere reference to the fact would seem a work of supererogation in a paper like this.

Not only have the germs or fungi of yellow fever been carried from an infected to a healthy community, but even the clothes of persons on dying from the disease have conveyed the germs, and infected, when exposed and handled, relatives and friends in healthy communities hundreds of miles away. You may denominate the contagion of yellow fever a contingent one; but it is nevertheless a contagion.

NOMENCLATURE.

Yellow fever, mal de Siam, typhus icterodes, malignant pestilential fever, Bulam fever, Mediterranean fever, etc., are among the names which have been applied to the disease under consideration. The eyes and skin are tinged with an orange hue earlier or later in a large proportion of cases; and this circumstance has given rise to the name by which the disease is known among English-speaking people as yellow fever.

It is a disease emphatically of one paroxysm, peculiar in its character, and should be classed among fevers of the *continued type*. Historically, it is a disease of towns, seldom or never assuming an epidemic character in the country or sparsely populated districts, and is therefore a local, and never a general, epidemic. The *materies morbi* has been stated already to consist of germs or fungi, which, in a certain temperature, may be communicated from one individual to another, and even conveyed by persons or clothing to great distances, sufficiently active to infect healthy unacclimated individuals and communities.

(To be continued.)

NOTES OF HOSPITAL PRACTICE.

CASE OF ABSCESS OF LIVER WITH ULCERATION OF COLON.

BY FRANCIS L. HAYNES, M.D.

THE following notes, giving the history of a case treated in the medical ward of the Episcopal Hospital during the service of Dr. Herbert Norris, are, I think, of sufficient interest to merit publication:

J. R., aged 48, a native of England, and by occupation a weaver, was admitted April 5, 1871. He stated that he had been sick for five weeks, during which time he had suffered from profuse diarrhœa; he had had a chill daily, "for some time." Although he had found his way to the hospital alone, he was extremely weak, and the powers of his mind were so much impaired that it was impossible to obtain any satisfactory history of his illness.

On the evening of admission the temperature was 103½°; pulse 128, very weak. The abdomen was tender on pressure, especially over the stomach and liver. Dulness on percussion existed over the base of the right lung, and crepitant râles were heard in that situation.

April 6.—Passed two liquid stools containing a considerable quantity of bright-red blood. One drachm of solution of morphia was directed to be given every four hours.

April 7.—Passed three yellow stools, all very liquid and containing numerous flocculi.

April 8 and 9.—No evacuations from the bowels occurred. His tongue, which had been coated white, assumed a brownish hue. He grew weaker and more stupid. Ecstasis was now noticed.

He expired on the afternoon of the 10th, immediately after a profuse hemorrhage from the bowels.

The treatment consisted in the administration of large doses of quinia, opium to check diarrhœa, alcoholic stimulus, and large quantities of liquid food.

RECORD OF TEMPERATURE AND PULSE.

	MORNING.	EVENING.		MORNING.	EVENING.
April 5, temp.		103½°	Pulse,		128
" 6, "	101½°	101°	"	128	120
" 7, "	98°	101°	"	114	120
" 8, "	101°	102°	"	138	138
" 9, "	102°	102°	"	136	138
" 10, "	102°	106½°	"	136	152

Autopsy, nineteen hours after death.—Rigor mortis well developed; body not emaciated; the dependent portions of the body and the anterior surface of the arms discolored blue.

Head.—Brain and its membranes presented marked venous congestion.

Thorax.—A small amount of serum in pericardial sac. Heart very flabby; loaded exteriorly with fat; a large "chicken-fat" clot occupied the tricuspid orifice and was intimately connected with the valve. The walls of the heart were softened, could be readily torn, and on microscopic examination presented marked fatty degeneration of the muscular fibres.

The right pleural sac was nearly filled with bloody serum; the lungs were somewhat congested, the base of the right lung intensely so; diaphragmatic and pulmonary pleura adherent on right side.

Abdomen.—Stomach normal, except that its epithelium presented under the microscope the appearance of fatty degeneration. The walls of the small intestine were very thin, and the epithelium of its lower portions had separated in the form of flakes.

The cæcum was thickly studded with circular ulcers, some quite deep, some superficial. They varied in diameter from one to one-eighth inch. A few ulcers were found in the ascending and transverse and one in the descending colon. The walls of the descending colon were very soft, nearly black in color, and their inner surface was covered with dark, thick blood. Rectum normal; mesenteric glands moderately enlarged.

The *liver* was enlarged, and weighed five and a half pounds. *On its convex surface, bounded above by the diaphragm, was a large abscess*, which contained eight fluidounces of thick gray pus. The walls of the abscess were very ragged, and presented no appearance of a limitary membrane. On microscopic examination the liver-cells were found to be distended by fat-globules.

TETANUS AFTER HYPODERMIC INJECTION OF QUINIA.—Two cases are recorded by Dr. Odevaine, in the *Indian Medical Gazette*. In the first case he employed sulphate of quinine dissolved in citric acid; in the second, neutral or soluble quinine, without any acid. An abscess formed in the situation of the puncture, followed by tetanus, and the death of the patient. Dr. Odevaine concludes that quinine exerts a special action on the nerves, or that the paludal cachexia, against which he was acting, exerts a peculiar influence on them.

TRANSLATIONS.

SYPHILITIC INFECTION WITHOUT COITUS.

A Clinical Lecture before the Berlin Medical Society, by PROF. LEWIN. Translated

BY DR. WM. ASHBRIDGE.

THE women and children presented at this lecture had all been infected with syphilis, but none of them by means of sexual intercourse. Some of the women shared their disease with their children, but it had also been communicated to them in other ways. For the sake of clearness and convenience, the nine patients were divided into several groups; the first group consisting of two women and their children. The first of these patients was an unmarried woman, in whom the disease manifested itself in a maculated and papular eruption, as well as in some other forms. Upon her under lip there was an induration the size of a bean. The second patient, a married woman with symptoms of constitutional syphilis, presented two similar indurations, one on either side of the nipple. These two parts, the under lip and the nipple, were in the respective women the points at which the disease made its entrance into the system. That this was true—that these indurations were really the seats of the initial lesions, and not later manifestations of the constitutional infection—was proved not alone by the subjective but also by the objective evidence adduced in the two cases. In regard to the subjective evidence (*i.e.*, the history of the case as given by the patient herself), the first patient, an unmarried girl of twenty, who had never before suffered from a similar affection, and had not been in the hospital nor under the observation of the police, gave the following history of herself. At the seventh month of her pregnancy, she noticed an apparently insignificant point of irritation upon her lower lip, which at first caused her no anxiety, but was very sluggish in healing, and, although it finally healed, left behind an induration. Some time before her own infection, she had noticed that the lips of her lover, who was the father of her child, were sore. After the birth of her child, occurring some weeks before the normal time, she noticed that it was weakly and covered with rashes and sores, and she was compelled to seek aid in the hospital.

The second patient, a married woman, the mother of three children, who up to this time had been healthy, stated that eight months after her last confinement, which had been a normal one at full term, she took to her breast a strange infant. Between three and four weeks later she noticed sores upon her nipple. As the infant, on account of an eruption, appeared to her to be of doubtful health, she sent it back, and shortly thereafter it died. On account of her own failing health, and more especially on account of the state of her child, which became affected with a sore tongue and with eruptions upon its skin, she sought assistance at the hospital. The positive proofs of the view that indurations must be looked upon as the seats of initial lesion, drawn from observation of the facts themselves, were as follows:

1. The condition of the lip and nipple, presenting the following conditions characteristic of the initial lesion of syphilis:

a. The consistence of a gumma of a medium degree of hardness.

b. The sclerosed mass deeply situated in the subcutaneous tissue, so that it is almost impossible to perceive any prominence of the induration over the level of the normal tissue by which it is surrounded. By this last condition it is distinguished from the broad condyloma, which, caused by a hypertrophy of the papillæ, always elevates itself more or less above the normal tissue about it.

c. A sharply-defined line between the induration and the surrounding normal tissue. By this means the diagnosis between the induration of a phlegmonous inflammation and that of syphilis can be made.

d. The characteristic dark-brown coloration.

2. The negative proof—*i.e.*, the total absence of any initial lesions upon the genitals, upon which could not be found any erosion, ulceration, or even scars or pigmented patches—goes far to strengthen the diagnosis.

3. The characteristic course of the implication of the glands. Instead of indolent swellings in the glands of the groin, these are noticed as being but little if at all affected, while those of the parts in which the infection took place are found much swollen and indurated. In the patient with the induration upon the lip, not only was the submental gland enlarged, but also the lymphatic gland situated under the angle of the jaw on the left side; the deeper glands also with which those of the face communicate, as well as those of the parotid region, showed marks of the same action.

In the second patient, in whom the initial lesion was on the nipple, numerous glands belonging to the lymphatic plexus of the axilla were found in the same condition, also scattered ones under the edge of the pectoralis major muscle, enlarged to the size of a duck's egg.

When the children of the two women were examined, they were found to be in the following condition: The one, the son of the unmarried woman, infected in the seventh month of her pregnancy, and at the time of examination three months of age, had been born two or three weeks prematurely, and presented the following symptoms: 1. General emaciation and weakness. 2. Swelling of the inguinal, cervical, and occipital glands, in varying degrees. 3. Traces of an eruption maculated and papular in its character. 4. Induration of the right testicle. 5. A symmetrical inflammation of the subcutaneous tissues on both legs on both sides of the tibia. In the second child, a boy aged thirteen months, who was born from a healthy mother, and who acquired syphilis at the age of eight months from the nipple of his mother, the following symptoms presented themselves: 1. A sharply-defined eroded induration on the left side of the point of the tongue, possessing the marks which have been already given as characteristic of an initial induration. 2. Swelling of the glands in the left submental and submaxillary regions. 3. An eruption maculated and papular in its character. Among the numerous conclusions that could be drawn from these facts, the following were brought prominently forward, but some of them only go to support observations already made: 1. That a true syphilitic infection can take place on any part of the skin or mucous membrane. This view of the possibility of infection without coitus was strongly combated by Ricord, who was often very satirical at the expense of those who made the exact observations by which the facts were established, particularly in the case of Waller of Prague. 2. That children born of mothers who have been infected in the latter months of gestation, as in this case in the seventh month, can be born with the so-called tertiary affections, to which class belongs the orchitis. The possibility that healthy children can be born under these conditions is not denied; but this case proves that the offspring of such mothers is not always healthy, as has been asserted by numerous authors. The pathological conditions found in this form of orchitis from congenital syphilis would be of interest and importance; but, so far as is known to Professor Lewin, the subject has not been investigated. Whether the condition of the skin upon the legs should have been looked upon as an integral part of the manifestations or not, was not

dwelt upon by the lecturer. 3. That we must receive with caution the view of numerous authors, who assert that in the greater number of children born with syphilis the disease is inherited only from the father, because the most accurate examination fails to reveal any trace of previous sores upon the genitals of the mother. The case of the girl with the primary affection upon the lips was a striking illustration of this, for there was nothing noticed on her genitals; even the glands of the groin and crural region gave no room for suspicion; attention was only called by the swollen condition of the submental gland of the left side, to the flat induration upon the lips, which was already skinned over and lay deep in the surrounding healthy tissues. 4. That women with so-called secondary syphilis can give birth to offspring suffering from so-called tertiary symptoms, the pathological conditions corresponding to which belong to a much more advanced step of the disease. This view, upon which doubt has been cast by many authors, is sufficiently proved by this case. 5. That the symptoms caused by hereditary syphilis present a greater intensity than those of the same disease acquired after birth: the child infected after birth has a stronger constitution, and is affected with rashes of the skin and mucous membranes; the second, with hereditary syphilis, in addition to a weakly constitution, suffers from organic degeneration which must be classed with the so-called tertiary manifestations.

TUBERCULOSIS OF THE LYMPHATICS.

By L. Thaon. Translated from *Le Mouvement Médical*, May 17, 1873.

TUBERCULOSIS of the lymphatic vessels is observed under a number of circumstances, which we will enumerate and analyze.

1. It is frequently found during the tuberculous inflammations of the strumous. The diseased lymphatics may then be seen under the microscope to be wholly superficial, lying almost under the epithelium or showing plainly in the sub-serous tissue. Klebs has experimentally produced on animals these tuberculous lesions of the peritoneal lymphatics, and has made histological studies of them with the aid of injections of silver.

2. In tuberculosis of the intestine, when the ulceration reaches a certain depth, nothing is more common than to see lymphatics, knotted, interlaced, and bleached, forming a net-work in the visceral peritoneum corresponding to the ulceration; thence they return to the glands which lie in the adherent border of the intestine, and pursue their course in the mesentery to be lost in the mesenteric glands. In one case of intestinal tuberculosis we have seen a lymphatic resembling a white, twisted cord, leaving an ulcer of the mucous membrane, and making a marked prominence for some distance before penetrating to the deeper layers.

3. In the diaphragm we have likewise seen numerous lymphatics invaded by tuberculosis during the course of a tuberculous diaphragmatic pleurisy. M. Lépine has pointed out the central tendon of the diaphragm as frequently the seat of tuberculous granulations. Now, at this point, according to Schweigger-Seidell, there exists between the tendinous fibres a tissue analogous to the reticulated glandular tissue. It would be interesting to know how tubercle is developed in this, and whether it undergoes the same evolution as in the glands.

4. We have said previously, when speaking of fibrous granulations of the lung, that Rindfleisch considered them the result of a lymphangeitis; we have denied the correctness of this view, and we confess that, to our great astonishment, we have never been able to observe anything in pulmonary phthisis which could be attributed to the lymphatics.

5. In a tuberculous testicle we have once discovered a large lymphatic filled with degenerated elements. It is, moreover, highly probable that the majority of granulations of the testicle arise at the expense of the epithelial cells which line the lymphatic spaces described by Ludwig, around the spermatic ducts.

We thus explained the appearance of a curious specimen presented to the Anatomical Society in 1872 by M. Reclus. It consisted of a testicle larger than a hen's egg, of a whitish color, composed of a series of cords some of which were almost one millimetre in diameter.

6. In two cases of tuberculosis of the female genitals we have observed a number of lymphatics similar to those of the mesentery in tuberculosis of the intestines. These lymphatics formed net-works under the serous membrane which covers the posterior face of the uterus and the wings of the broad ligament.

7. In the brain the granulations are developed in the lymphatic peri-vascular sheath, which we know to be the equivalent of the lymphatic vessels of other organs.

To sum up, the lymphatics play an important rôle in tuberculosis. Sometimes they are limited to serving as canals for the transportation of the infecting materials which go to the glands; at other times they themselves take part in the tuberculosis, constituting *tuberculous lymphangeitis* mixed with *granulations*. These lesions may easily be studied on specimens hardened with Müller's solution, gum, alcohol, and on sections colored with picro-carminate of ammonia. They are very exactly described in the manual of MM. Ranvier and Cornil (p. 582): "In the first stage the lymphatic vessels are filled with white globules and with cells of various forms proceeding from the vascular epithelium; the walls of the latter and the adjoining connective tissue are to a great extent filled with embryonic cells. In the second stage the cells collected in the walls of the lymphatics and in the connective tissue form, with the cellular contents of the vessels, a nodule having all the characters of a tuberculous granulation. These nodules placed in the track of the lymphatics are more or less distant from each other, and have been in many cases confounded with granulations arising from the connective tissue." Let us add that nearly all this work of proliferation is done at the expense of the lymphatic endothelium, and that we are occupied with a veritable caseous endo-lymphangeitis mixed with granulations.

Cutaneous Absorption of Poisons.—In a recent note to the Paris Academy, M. Bernard describes a series of experiments for the purpose of testing the degree of cutaneous absorption which took place in a bath impregnated with the substances to be tested. Every precaution was taken to prevent the possibility of the substances entering the system of the patient by any avenue except the skin. He was then submitted for a short time to steam vapor charged with iodide of potassium, and two or three hours afterwards the urine gave unmistakable evidence that the iodide had been absorbed and was passing through the system.

In these experiments the medicinal agent reached the skin in hot aqueous vapor, and therefore acted more readily than an ordinary cold solution; but the fact of cutaneous absorption was very definitely illustrated. M. Bernard adds,—

"M. Colin has described an experiment in which he allowed water charged with cyanide of potassium to fall for five hours on a horse's back. This caused the death of the animal; the sebaceous (fatty) matter having been destroyed through percussion, and cutaneous absorption taking place."

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 16, 1873.

EDITORIAL.

SPLINTS.

IN a recent admirable article in the *Popular Science Monthly*, Mr. Herbert Spencer attempts to explain the persistence of the mechanic arts among rude peoples, by comparing the products of their labor with some of the thoughtless repetitions of imperfect models so common among the workmen of to-day. We can all testify to the intractableness of the American mechanic, particularly of him who is the power in the cutler's shop. Liberal wages have had little effect, apparently, in stimulating his inventive powers or inducing him to carry out the conceptions of the practitioner who may employ him, and the surgeon is often compelled to devise the patterns of his instruments, leaving to the artisan merely the work of giving them durable shapes. Mr. Spencer could not complain of exact adaptation of means to end in this branch of industry. Unfortunately, the motive of the inventor is often to fix his name to an apparatus, rather than to improve a method of treatment. Jones is no longer satisfied with Brown's modification of Smith's splint; so he writes a paper asserting the value of a certain hook or screw, and counts the result as fame,—often neglectful of the fact that some other worthy had better described the same point long before.

The average mind is surprisingly fertile on the subject of splints. This was exemplified at a recent meeting of the American Medical Association. The session of the surgical section had been unwontedly dull, until a member began to discuss the treatment of fracture, when it was discovered that there were present many gentlemen who were authorities on the subject. An incontinent discussion ensued on the comparative merits of splints of starch, wood, wire, paper, glass, and plaster, until the gavel of an exhausted chairman checked it in order that the business of the section might proceed. It has been said of the author of a single book that he was the publishers' measles, since they had had him but once. Many surgeons would appear to believe that they *must* invent a splint, at least once; but, as a prophylactic in such cases, we would commend the perusal of a paper by Dr. Edward Hartshorne in a recent volume of the *American Journal of the Medical Sciences*, on the bibliography of the treatment of fractures of the femur by extension. Let them ponder and be wise.

The effect of this over-inventiveness is to give an unscholarly tone to an important department of medical literature, to say nothing of the minor evil of encumbering the practitioner's office with apparatus about as useful as the ends and fragments depicted in Hogarth's "Finis." All credit to those who contribute to our stock of improved appliances; but candidates for such regard should be sure of the justice of their claims before placing them on record.

THE WILLS HOSPITAL.

THIS useful charity is dispensing its benefits to an annually increasing number of patients. It is stated in the report for 1872, recently issued, that during the year there were treated 362 in-patients and 2514 out-patients, and that 628 operations were performed.

This hospital was opened in 1834, through the liberality of James Wills, "for the sole use of the indigent blind and lame," and, in accordance with the express terms of his will founding the institution, it was denominated "*The Wills Hospital for the Relief of the Indigent Blind and Lame.*" From the report for 1872 it appears that the title has been changed—by what authority we know not—to *Wills Ophthalmic Hospital*, from which we infer that the lame are hereafter to be excluded from the benefits of the institution,—an inference strengthened by the fact that no cases of lameness are reported to have been treated at the hospital during the past year.

That the lame of Philadelphia need hospital accommodation is proved by the large number who are annually treated at the Orthopædic Hospital, an institution whose recent foundation may have

been rendered necessary by the non-treatment of orthopædic cases at the Wills Hospital.

We have no doubt that the funds dedicated to the hospital are well administered; but there are so many questions, legal and otherwise, connected with the management of charitable bequests, that it would seem only prudent for those concerned to obey the letter as well as the spirit of the testator's wishes.

IT is not often that rogues disgorge ill-gotten plunder. It is stated, however, by the London *Times* that Dr. Holloway, of pill and ointment fame, is devoting the enormous sum of 350,000 pounds sterling to the erection of lunatic and other hospitals. It is well to undo, as far as possible, what is wrongly done. But, before we praise the munificence of this patent-medicine vendor, we would like to know how much he retains of the money wrung from misery by false hopes and promises. As the world goes, we suppose, however, Dr. Holloway will reap his reward. The man who gulls the multitude in so royal a manner must be smart, though he be unprincipled; and successful smartness is the talisman to outward homage. After all, however, the doctor must know that he is but a "quack doctor," and that the men who bow before him know it also.

THE South of France does not appear to be a paradise for careless pharmaciens, as is shown by the account of a recent transaction given in the *Bulletin Commercial de l' Union Pharmaceutique* for June. It seems two ladies were poisoned by stramonium given for saponaria by an apprentice. Although they recovered without serious consequences, the *ministère publique* censured the unfortunate apothecary in very severe terms, and the police court sentenced him to a fine of two hundred francs. Worse still, the two ladies have sued for damages to the extent of twenty thousand francs. As they promise to give the money to charities, supposing that French juries are like those of America, the apothecary, if he be rich, had better compromise the civil suit.

TEST FOR IMPURITIES IN WATER.—An English technical periodical says, "Good water should be free from color, unpleasant odor and taste, and should quickly afford a lather with a small portion of soap. If half a pint of the water be placed in a perfectly clean colorless glass-stoppered bottle, a few grains of the best lump white sugar added, and the bottle freely exposed to the daylight in the window of a warm room, the liquid should not become turbid, even after exposure for a week or ten days. If the water become turbid, it is open to the grave suspicion of sewage-contamination; but if it remain clear, it is almost certainly safe. We owe to Heisch this simple, valuable, but hitherto strangely neglected test."

REVIEWS AND BOOK NOTICES.

THE LOCAL USE OF TAR AND ITS DERIVATIVES, INCLUDING CARBOLIC ACID, IN THE TREATMENT OF SKIN DISEASE. By L. D. BULKLEY, A.M., M.D., Physician to the New York Dispensary for Cutaneous Diseases. Reprinted from Dr. Brown-Séquard's Archives of Scientific and Practical Medicine, April, 1873. J. B. Lippincott & Co., New York and Philadelphia. Pamphlet, pp. 25.

In this little pamphlet, which is a welcome contribution to the therapeutics of diseases of the skin, the practitioner will find much useful information which has hitherto been scattered through journals and special works on dermatology.

Dr. Bulkley gives a concise account of the different varieties of wood tar, the pix liquida of the U. S. P., ol. picis, ol. cadini, ol. rusci, and ol. fagi; as well as their source, their preparations, and their application. Then, after devoting a few pages to their therapeutical indications, he goes on to speak of their derivatives—pyroligneous acid, acetic acid, creasote, pitch, turpentine, resin, and resineon—in the same manner. Giving a brief notice of the uses of coal tar, he goes into a consideration of its derivatives, carbolic acid and petroleum, the former at some length.

Dr. Bulkley shows the beneficial effect of the use of tar and its derivatives in the later and less acute stages of eczema, as well as in psoriasis, prurigo, and the various parasitic skin affections. He very properly suggests withholding these preparations in the acute stage of eczema, at which period their incautious use has frequently resulted in marked aggravation of the inflammatory symptoms.

The occasional want of toleration which is shown by some skins towards these preparations is alluded to; a fact worthy to be remembered, in order that where a large extent of surface is involved in disease, an experiment may first be made on a small portion of the skin before the more general use of the application.

Dr. Bulkley introduces to the notice of the profession a preparation which he has named "liquor picis alkalinus," being essentially a watery solution of tar by means of caustic potash. This solution is said to have been used with advantage in the various stages of eczema, in psoriasis, and in lupus erythematosus: it certainly seems worth a more general trial.

On one point we must be allowed to enter a mild protest, and that is against the use of the word "petroleum" to indicate the fluid usually sold for illuminating purposes and generally known as "kerosene." The term "petroleum" is properly applied to the crude product drawn from the oil-wells of Pennsylvania and other localities, from which most of the "kerosene" or "coal oil" of commerce is derived by a process of distillation.

A. V. H.

BODY AND MIND: an Inquiry into their Connection and Mutual Influence, especially in Reference to Mental Disorders. A New and Revised Edition, to which are added PSYCHOLOGICAL ESSAYS. By HENRY MAUDSLEY, M.D., Professor of Medical Jurisprudence in University College, London. London, Macmillan & Co., 1873.

In this new edition of a well-known book the changes consist in the introduction of essays on "Conscience and Organization," on "Hamlet," and on "Swedenborg;" and we must confess that the additions strike us as being even more interesting and instructive than the original Gulstonian lectures on "Body and Mind," which form the *pièce de résistance* of the work. We would not like to be forced to choose between the stake and the full acceptance of Dr. Maudsley's doctrines; but, so long as

variety may be enjoyed without suffering, we will continue to derive pleasure both from our own opinions and the highly suggestive papers of the learned professor.

The essay upon Conscience and Organization is an extremely important one, and certainly shows most clearly what we suppose no medical thinker will deny, that wickedness—moral insanity, if you choose—is very often dependent upon an improperly organized brain; but this does not prove that it is always so, much less that conscience is simply the product of organization. The most skilful musician will produce discords if his instrument is out of tune; and if there be such an entity as a *spirit* in man, the manifestations of that spirit must be influenced by the disorders of the system through which it acts. Ergo, the having proved that a physical derangement affects or disturbs the workings of conscience is, by itself, no step towards proving that conscience has not a distinct spiritual existence; and just at this point on which the materialistic argument breaks is the chasm which separates the scientifically knowable from the scientifically unknowable.

Swedenborg our author shows to have been a madman, with a streak of genius in his insanity, and a tinge of obscenity borrowed from remembrances of the companions in dalliance with whom he spent the leisure hours of his youth and middle age. If, as his followers assert, he drank deeply of spiritual joys, he certainly reserved them until, for him, the fountains of carnal pleasure were exhausted.

We have often wondered for what object many book notices are written, and have concluded that it is frequently to fill up the columns of a journal, to gratify personal spite, or to contrast the profundity of the critic with the author's lack of wisdom. We conceive, however, that the proper motive, the originating reason, so to speak, should, in a journal like this, be duplex,—to express an opinion as to the merits of the work, and to enable readers to determine whether they do or do not desire to purchase it.

We commend this book, then, as the functional excretion of a delicately organized cerebrum, whose cell-structure has evidently been improved by high culture. As to buying it, reader, if you belong to that class of miserable mortals who see nothing more in our profession than a philosopher's stone by which the transmutation of nauseous drugs into wholesome bread and butter may be accomplished, you need not buy this book. If you want to be more than this,—a thinking, reasoning representative of the highest science, that which deals with humanity,—buy the book, or at least read it. Understood aright, it will widen your thought, deepen your sympathy, and increase that reverent humility which the true man of science always feels when he approaches the boundaries between the finite and the infinite.

GLEANINGS FROM OUR EXCHANGES.

Physiology of the Biliary Secretion.—Röhrig contributes a paper on this subject to the last part of Stricker's *Medizinische Jahrbücher* (Heft ii., 1873). His experiments were conducted on dogs and rabbits fully under the influence of curara. A bent-glass tube was inserted into the ductus communis choledochus in a large curarized rabbit, in which artificial respiration was maintained. He obtained, at the commencement of an experiment lasting about half an hour, one drop of bile every eight seconds, but at the close only one drop in every seventeen seconds. The last-secreted bile was more intense in color than the first, and was more glutinous. Compression of the vena portæ, or of the hepatic artery, or of both together, caused an immediate diminution of the quantity of the secretion, but after some time, though the compression was continued, the liver recovered its activity to some extent. A rabbit which yielded one drop of bile in about twenty-four seconds before compression only yielded one drop of bile per seventy seconds after; and a dog previously giving one drop in thirty seconds only gave one per eighty or ninety seconds after compression. Ligation of the thoracic aorta just above the diaphragm reduced the secretion in a dog from one drop in seven seconds to one in fifty. Ligation below the cœliac axis raised the rapidity of the secretion from one drop in eight seconds to one drop in three seconds in a rabbit. Compression of the vena cava ascendens, so as not completely to arrest the flow of blood, caused steady diminution of the flow of bile from one drop in five seconds to one drop in thirty-two seconds. On releasing the vein it again steadily rose to one drop in four seconds. The opposite effects obtained from ligature of the venæ cavæ and compression of the aorta demonstrate, Röhrig thinks, that the formation of the biliary secretion is not exclusively dependent upon the degree of pressure in the capillaries, but rather upon the current and quality of the blood. Injection of water into the intestinal canal increases the biliary secretion, and to a greater extent than the injection of the same quantity into the blood-vessels. Irritation of the mucous membrane of the intestinal canal in various parts from the mouth to the anus, as well as of the peritoneum, was not attended with any very definite results. Digestion always increased the quantity secreted considerably, and when the partially digested contents of one dog's stomach were injected into that of another, the quantity of bile began to rise rapidly in ten minutes. Croton oil, colocynth, jalap, aloes, rhubarb, senna, sulphate of magnesia, calomel, and castor-oil, all increase the flow of bile; the two latter, however, only feebly, the first two vigorously. Section of the splanchnic nerve caused increase of the biliary secretion; neither section nor irritation of the vagi sympathetici had any influence on the amount. Division of the spinal cord was followed first by increase and then by retardation of the flow. Indirect irritation of the spinal cord by electricity prolonged the periods between the drops. Suspension of the respiration was variable in its action, but, as a rule, retarded the secretion. Opium rather increased the flow of bile by its paralyzing influence on the peripheric vessels; it checked diarrhœa by its action on the peristaltic movements.

Treatment of Chilblain by Electricity.—Dr. Santopadre makes known, in *Gaz. Med. de Provincie Venete*, a means which he has employed with success for the treatment of chilblain,—namely, electricity. He makes use of Gaiffe's electro-magnetic apparatus, and of a current of middling intensity. The positive pole is placed in the neighborhood of, and a little above, the inflamed spot, and the negative pole to the inflamed spot itself. The sitting lasts about ten or fifteen minutes, and is repeated if necessary the following day. Generally after the very first sitting the itching ceases and the pain is much abated. After the third or fourth sitting recovery is complete.

Contribution to the Pathological Anatomy and Physiology of Urinary Tumors and Abscesses.—In a communication to *Le Mouvement Médical*, M. Henri Dransart, *interne* of the Paris hospitals, gives the following propositions as the results of his clinical observations and dissections:

1. Chronic blennorrhagia produces a sclerosis or cirrhosis of the urethral spongy tissue.

2. Sclerosis of the spongy tissue results in the disappearance of the cavities, and in a new vascular forma-

tion like that seen in cirrhosis of the liver or of the lung; the vessels are less numerous, of small calibre, and have young and feeble walls.

3. There occur in the submucous tissue hemorrhages whose mechanism is explained on the one hand by the function of the organ,—coitus and other acts,—and on the other by the nature of the newly-formed vessels which nourish the fibrous tissue.

4. These hemorrhages are the origin of a large number of the tumors and urinary abscesses which occur during the existence of strictures. We can easily conceive that they may be very slight and occasion merely phenomena of engorgement in the substance of the submucous tissue of the urethra.

He states that Chopart was familiar with this cirrhosis or fibrous degeneration of the spongy tissue, and designated it as "scirrhous degeneration," a difference merely in the name. M. Voillemier has pointed out the occurrence of hemorrhages in the new tissue, but has not sought to explain their originating cause, which lies in the nature of the vessels replacing the primitive vascular apparatus. The development of new branches of the bronchial and hepatic arteries in cirrhosis of the liver and lungs enters to-day into the crudest notions of pathological anatomy; and this science has also taught us that vessels of a new formation usually have feeble walls. These facts being known and applied to the urethra, whose special functions are understood, hemorrhages and the tumors and abscesses which are their sequelæ might be reasonably anticipated.

M. Trélat on the Operations for Phimosis.—M. Trélat, Professor of Surgical Pathology at the School of Medicine, and Surgeon to the Hôpital La Charité, lately delivered a very interesting lecture on the treatment of phimosis. He premised his lecture by a few remarks on the etiology, or rather the pathology, of phimosis, which, he stated, consists of two forms,—the congenital and accidental. It may be also complete or incomplete. In the former, the preputial orifice is so contracted as to prevent the free passage of the urine, or the phimosis, without extending to that degree, may just be sufficient to prevent the uncovering of the glans, and thus favor the accumulation of the secretions, constituting the condition termed balanitis; or, when the prepuce is forcibly drawn back over the glans, it produces paraphimosis. For both forms of phimosis operative measures hold out the only chance of cure. For the congenital form, forced dilatation, as recommended and practised by Nélaton, may be useful, but for that produced by disease it is out of the question. In either case M. Trélat prefers the radical cure, by circumcising or slitting up the prepuce, as he considers the dilatation plan as being not only a most awkward operation, but one which affords only temporary relief, after which relapses almost invariably occur, and which is frequently followed by paraphimosis. As the best proof that can be given of the necessity of an operation, M. Trélat stated that he has known old men who, after having borne the complaint for years, were obliged at last to submit to an operation. He had operated on three old men, aged respectively 63, 64, and 67. The prepuce of the last subject had a most unnatural appearance, as it had become hard and gristly, and considerably hypertrophied, and when this portion of the prepuce was removed by circumcision it was impossible to bring the skin and mucous lining together, and the wound in consequence was more than two months in healing. At what age may phimosis be operated on? is a question often asked; and M. Trélat thinks that there are three periods at which the operation may be conveniently performed, viz., from three to seven, from eighteen to twenty-five, and then in old men who are the subject of chronic balanitis. In children it is best to defer the operation as long as possible,—unless the phimosis is attended with great inconvenience, such as the accumulation of urine between the glans and foreskin, and consequent balanitis, or if the young subject is given to masturbation,—as the difficulty of the operation consists in the keeping the two cut edges in apposition. M. Trélat performs circumcision when the phimosis is simple, that is, when there is simple prolongation of the foreskin, accompanied with only slight contraction of the orifice; but when the phimosis is attended with the inconveniences mentioned above, he adopts the slitting plan; and, if the prepuce is long and thickened, he snips off the two ends that overhang each side. In this operation M. Trélat remarked that the foreskin should be slit well up to the corona glandis, otherwise the phimosis remains uncured, and after a time the patient comes back justly dissatisfied with the surgeon and demands a renewal of the operation. The incisions made, he applies a certain number of serrefines (from ten to fifteen), which he prefers to sutures: they, however, should be kept on for only a short time. In general, he removes them at the end of twenty-four hours, for if kept longer they are liable to produce sphacelus. —*Irish Hospital Gazette*, July 15, 1873.

Homœopathic Pilules (*The Practitioner*, July, 1873).—The most careful chemical analyses have failed to demonstrate the presence of either aconite, atropia, or belladonna in pilules which professedly contained in one hundred parts one part by weight of the drug. Comparative experiments showed that $\frac{1}{8000}$ of a grain of aconite would have been detected with certainty. This corresponds to about $\frac{1}{160}$ of a grain of the extract of aconite; while the quantity which should have been present is from $\frac{4}{5}$ to nearly one grain, or more than one hundred times more. Similarly, $\frac{1}{6000}$ of a grain of atropia would have been discovered,—twenty-four times as much was supposed to exist in the preparation.

We would certainly be obliged to place cures, should there be any following the use of such pilules, entirely to the credit of the imagination.

Injections of Alcohol into Fatty Tumors (*Medical Press and Circular*, May 21, 1873).—Dr. Hasse, of Nordhausen, recommends the injection of alcohol into the substance of adipose or lipomatous tumors. He gives one case of a female who had a large fatty tumor reaching from the shoulder to the armpit. He injected alcohol into this at four different sittings, with fifteen days' interval, directing the syringe into different parts of the tumor. In a few days there was some slight inflammation. The tumor at first became firmer, but soon softened and fluctuated at several points. In three weeks an incision was made, and the fatty matter could be pressed out in a liquid form. In another case, of a man aged forty, similar treatment was adopted, with a similar result.

Temperature in Epilepsy and Hysteria (*Le Mouvement Médical*, No. 11).—Dr. Bourneville states that he has satisfied himself, from observations taken in the Salpétrière and St. Louis Hospitals, that during an attack of epilepsy the temperature augments; so also in attacks of epileptiform hysteria the temperature rises. On the contrary, in pure hysteria there does not appear to be any increase. He thinks that by this means it is possible to distinguish an attack of true from one of feigned epilepsy. When the disease is simulated, the attacks are always the most severe possible, yet the temperature does not rise above the physiological degree; but when the real attacks are severe, the temperature not only rises during the fit, but remains above the normal for several hours.

MISCELLANY.

Obscene Literature.—The following extract from a letter, dated January, 1873, by Mr. Anthony Comstock, of Brooklyn, to Hon. Clinton L. Merriam, shows that the law recently passed by Congress is doing good. Mr. Comstock says,—

"These I have seized and destroyed: Obscene photographs, stereoscopic and other pictures, more than 182,000; obscene books and pamphlets, more than five tons; obscene letter-press in sheets, more than two tons; sheets of impure songs, catalogues, handbills, etc., more than 21,000; obscene microscopic watch- and knife-charms and finger-rings, more than 5000; obscene negative plates for printing photographs and stereoscopic views, about 625; obscene engraved steel and copper plates, 350; obscene lithographic stones destroyed, 20; obscene wood-cut engravings, more than 500; stereotype plates for printing obscene books, more than five tons; obscene transparent playing-cards, 5500 to 6000; obscene and immoral rubber articles, over 30,000; lead moulds for manufacturing rubber goods, twelve sets, or more than 700 pounds; newspapers seized, about 4600; letters from all parts of the country, ordering these goods, about 15,000; names of dealers in account-books seized, about 6000; arrests of dealers since October 9, 1871, over 50; publishers, manufacturers, and dealers dead since March last, 6.

"There are various ways by which this vile stuff has been disseminated. First, by advertising in the above-named papers. Some weeks there is not a single advertisement in some of the papers that is not designed either to cheat or defraud, or intended to be a medium of sending out these accursed books and articles. For instance, I have arrested a number of persons, one in particular, who advertised a musical album, to be sent for fifty cents. I sent the fifty cents, and received back a catalogue of obscene books, with the following card attached:

"'The album is only a pretence to enable us to forward you a catalogue of our fancy books. Should you order any of these books, your fifty cents will be credited.'

"It is needless to say, I ordered, then arrested him, locked him up in the New Haven jail, and he has been indicted by the grand jury in the United States Court of Connecticut, and now is held on bail for trial. In the same way, by advertising beautiful views or pictures of some celebrated place or person, these men receive answers from innocent persons for these pictures, and among the pictures sent will be one or more of these obscene pictures, and catalogues of these vile books and rubber goods. For be it known that wherever these books go, or catalogues of these books, there you will ever find, as almost indispensable, a complete list of rubber articles for masturbation or for the professed prevention of conception."

Practice and Pregnancy.—A rather amusing story is current just now about a Mrs. Anderson, which serves to illustrate the ground of English prejudice to feminine invasion of male pursuits. Mrs. Anderson has been married now for about two years, and, as she is a person of some note, socially and professionally, she is much talked about. It was lately very generally reported that she was likely soon to be a mother. For some reason, she seemed to think that such a report ought not to be allowed to pass uncontradicted, and she has adopted the remarkable step of writing to a physician, who was one of those who had repeated the rumor, denying its accuracy, and requesting that he would take proper occasion of contradicting a statement which was likely to be injurious to her practice. This seemed to me incredible, but it has been confirmed as a fact; and the notion that a married woman should think it due to herself to contradict the statement that she was *enceinte*, has a sad and serious as well as a ludicrous side of it, to those who think that the highest ambition of any woman is to become a mother, and that the greatest misfortune which can happen to her is to fail in that high mission and noble ambition of womanhood and wifehood.—*London Letter to Boston Journal.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 29, 1873, TO AUGUST 11, 1873, INCLUSIVE.

Simons, J., Surgeon and Medical Director.—Granted leave of absence for thirty days, with permission to apply for an extension of thirty days. S. O. 124, Department of the Gulf, July 28, 1873.

Frantz, J. H., Surgeon.—Leave of absence extended from July 20, 1873, seventy days, on Surgeon's certificate of disability. S. O. 153, A. G. O., July 29, 1873.

Webster, Warren, Surgeon.—Granted leave of absence for thirty days. S. O. 143, Department of the East, July 28, 1873.

Knickerbocker, B., Assistant-Surgeon.—Leave of absence granted by S. O. 88, Department of the Columbia, July 15, 1873, extended thirty days. S. O. 135, Military Division of the Pacific, July 23, 1873.

Cleary, P. J. A., Assistant-Surgeon.—Assigned to duty at Fort Griffin, Texas. S. O. 139, Department of Texas, July 25, 1873.

Munn, C., Assistant-Surgeon.—Assigned to temporary duty at Fort Independence, Boston Harbor, and to return to his proper station (Fort Adams, R. I.) when Surgeon Webster reports from his leave. S. O. 143, c. s., Department of the East.

Simpson, John, Surgeon.—Granted leave of absence for three months, on Surgeon's certificate of disability. S. O. 163, A. G. O., August 9, 1873.

Simons, J., Surgeon and Medical Director.—Leave of absence extended thirty days. S. O. 45, Military Division of the South, August 5, 1873.

Alexander, C. T., Surgeon.—Granted leave of absence for thirty days. S. O. 162, A. G. O., August 8, 1873.

Wolverton, W. D., Assistant-Surgeon.—Relieved from duty in Department of Dakota, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 158, A. G. O., August 2, 1873.

Smart, Charles, Assistant-Surgeon. — Assigned to duty at Fort Bridger, Wyoming Territory. S. O. 129, Department of the Platte, August 5, 1873.

Cleary, P. J. A., Assistant-Surgeon.—Relieved from duty in Department of Texas, and to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 160, A. G. O., August 6, 1873.

Wiggin, A. W., Assistant-Surgeon.—Granted leave of absence for thirty days, with permission to leave limits of Department and apply for an extension of thirty days. S. O. 95, Department of the Columbia, July 28, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE RELATION WHICH FAULTY CLOSET-ACCOMMODATIONS BEAR TO THE DISEASES OF WOMEN.

BY WILLIAM GOODELL, M.D.,

Physician-in-Charge of the Preston Retreat; Clinical Lecturer on the Diseases of Women and Children in the University of Pennsylvania, etc.

"THE sublime," writes the great Burke, "is an idea belonging to self-preservation." Emboldened by this definition, I shall offer no apology for addressing you this morning upon an unsavory subject. For it is one—as I hope to prove—closely allied to the moral and physical well-being of the mothers and daughters of this land, to the vigor of their offspring, and, as a consequence, to the health and happiness of the community, and to the strength of the state.

The important question of sewage- and cesspool-diseases, which is now agitating political economists, has a range far wider than those branches of medicine on which I lecture. I shall, however, limit my remarks to that aspect of it which directly concerns the good health, and more remotely the good morals, of women,—viz., *the relation which faulty closet-accommodations bear to the diseases of women.*

In adults the state of health denotes a state of equilibrium between waste and repair,—between construction and destruction. But the statical condition is one necessarily disturbed by the smallest casting-weight. Hence very slight indeed may be the cause which deranges the nicely-balanced relation between the functions of the various organs of the body. Thus, by the imperfect and unpunctual performance of the excretory functions, our food becomes our poison. The lengthened detention of fæces in the bowels, or of the urine in the bladder, begets a host of disorders, in man as well as in woman. But it is in the latter that they are most manifest. Irregularity or postponement in the evacuations of the body is perhaps the most common cause of uterine and pelvic diseases. For not only are local congestions produced mechanically by the irritation or the pressure from hardened fæces, and flexions of the womb brought about by the straining efforts to empty the bowels; but the intimate interdependence between the pelvic and the uterine plexus of veins on the one hand, and the portal system on the other, is at the root of all manner of female complaints. A congestion in the one determines in the other a like condition, which in turn confirms and augments the disorder of the former. It is, indeed, astonishing how quickly a woman's health declines from inattention to habits of regularity.

Over-distention of the bladder, by drawing up the cervix and by thrusting the fundus backward, is undoubtedly a very common factor in the production of retroflexions and retroversions of the womb. Almost every acute case of uterine displacement and many cases of vesical catarrh are thus brought about. The very worst case of irritable bladder that I ever met with occurred in a lady who, thirty years previously, had travelled a whole day in a stage-coach without finding a fit opportunity for passing her water.

Again, costiveness is the recognized cause not only of hemorrhoids, of pelvic and uterine congestions, and of disorders of the digestive apparatus, but also of fæcal poisoning. For if diseases breed from bad drainage and defective sewerage from without the body, how much more from bad drainage and defective sewerage within the body! Excretions retained in the body ferment and decompose; the pestilential gases thus generated, and the products of tissue-waste, being resorbed, degrade the blood, disable nerve-centres, and paralyze the action of vital organs. A mischievous reciprocation takes place, by which the cause and its effects aid and abet one another. Take for instance the liver: costiveness makes it secrete less bile, and this torpidity not only causes a uterine congestion, but also reinforces the habit of constipation. So, in a measure, with every other organ: blood-disorder leads to morbid nutrition of nerve-centres, and this in turn still further degrades the blood. Thus is evoked that exaltation of nervous action which so often becomes turbulent and uncontrollable. Hysteria, chlorosis, and climacteric perturbations are always linked with defective hæmatosis.

Except as the result of this vicious circle, how else explain the proverbially bad health of women living in the country, and of the poorer classes of women in cities? Show me such a woman, and you show me a costive creature, one whose whole life is spent in an unnatural struggle with the lower but needful calls of her body. This evil is in itself bad enough; but, unfortunately, it does not end there. Upon the good health of the mother depends the good health of the child. Feeble mothers beget feeble children,—children who are carried from the womb to the grave, or who peak and pine under the heritage of ill health.

Such, then, being the condition of the majority of American women, what is the cause? "Probably no single cause," writes a close observer, "has had so much influence in producing the peculiarly delicate condition for which women living in the country and in the small towns in America are notorious, as the discomfort, inconvenience, and frequent repulsiveness [and, I may add, indecent exposure] of their closet-accommodations."

The ancients, who were wiser in their generation than we in ours, set examples which we in the nineteenth century might in some respects usefully follow. The cloacæ of Rome are still the admiration of the architect. They were built so firmly as to have resisted the impetuous torrents of over seven hundred winters. To keep them in repair, public officers were appointed, who were called the *curatores cloacarum urbis.* Even a goddess—the fair Cloacina—was chosen to preside over them. But with us how different!

In the teeming tenement-house of any of our large cities there is usually but one closet, and that invariably a cesspool, wet and foul, reeking with filth, poisoned by noisome stenches, defiled by lewd couplets or obscene cuts, indecent from thin partitions and wide chinks, or from being preoccupied by one of the opposite sex. Under such conditions, what woman can avoid schooling herself into the habit of resisting the evacuation of her bowels? In the small houses of tradesmen and of mechanics the water-closet is rarely to be found; nor are the houses of the better classes always supplied with this luxury. The privy is, then, usually placed at the farther end of the yard, and approached by a long and unsheltered path. It is, therefore, almost inaccessible in bad weather or in dark nights, and is overlooked by the back-buildings of all the neighboring houses. To a delicate woman the exposure to the weather is a serious inconvenience; to one who is menstruating, it is a constant menace; while to every refined woman the exposure to view offers but one of two choices,—either that of having her sense of modesty blunted, or that of waiting until nightfall before responding to the calls of nature.

Nor does the condition of the closets in the country present a more agreeable contrast. In many parts of the Southern and Western States a clump of bushes, the shelter of a rock, the nearest grove, afford the only accommodations. But take the more thickly-settled States: where is the small farm-house whose privy invites rather than repels? The very name of *privy* is a misnomer. How seldom is the building hidden by clumps of evergreens or masked by any other disguise than that of a euphemism! How often is it not at an embarrassing distance from the house,—at the end of a long trail, or, at best, of a long and ill-kept path, which frequently runs parallel with a street or a road! How rarely is it ever provided with any other kind of window than round or crescent-shaped holes rudely cut out of the door! How commonly are the cracks dehiscent! The door itself is often without a bolt, often hanging by one hinge,—sometimes wholly unhung. Through the openings in the seat acrid blasts of wind sweep up as if impelled by some malignant demon. Now, add to all this the sickening stench, the conspicuous heaps of filth, the swarms of unclean flies, and confess that, despite the temerity of the description, the picture is not overdrawn.

Imagine now broad daylight with its busy traffic, a rainy day or a dark night, the grass wet with dew or the ground covered with snow, or the temperature, perchance, many degrees below zero. Under such circumstances, what woman can respond to the calls of nature without putting herself to great discomfort, to great risk, indeed, if she be menstruating, or without blunting the edge of her womanly sense of decorum?

Nor is this last phase of the subject the least important. The shrinking from publicity in the performance of these functions is neither "prudery" nor "false modesty," but a virtue of which our women may well be proud. In those countries where woman most disregards it, there is she least chaste, and there is the license of language least bridled. Whatever refines the body refines the mind, and *vice versâ*. The one reacts upon the other for better or for worse. Our forefathers, who scorned clothing and cleanliness, and who eased themselves, like their cattle, wherever the desire seized them, were in appetite little better than cannibals, in temper and morals lower than the brutes. When they began to wash themselves they began to clothe themselves; and after the culture of the body that of the mind followed as a matter of course. Thus soap becomes a great civilizer. "Show me," said the great Liebig,—or in words to this effect,—"Show me the nation which consumes the most soap, and you show me one which has reached the highest grade of civilization." So with regard to closets. "Show me," say I, "the nation that gives the most comfort, the most privacy, the most solicitation, to the evacuations of the body, and you show me, in refinement, in education, and in morality, the foremost people on the face of the earth."

I have told you the bane; now, what is the antidote? Clearly, *such closets as invite rather than repel*,—closets in which an operation of the bowels is not tantamount to being buffeted of Satan for a season. In cities, and in such towns as are supplied with water-works and good drains, the use of the water-closet ought to become universal. In the country, where such a luxury can be attained by the rich alone, the earth-closet is the only substitute; and I cannot too strongly urge you to advise its use among your patients and neighbors. Set the example by using one yourselves; you will soon get back more than its money's worth of comfort, health, and privacy.

Although, at my request, this gentleman has kindly consented to exhibit to you the mechanism of his earth-closet, yet I am not the advocate of his patent, or of any one of the patents now in the market. You must select the one which seems to you to meet best all the requirements. I am contending simply for the principle on which these earth-closets are based, and for the moral and hygienic advantages which they offer. A portable closet, like this one, not larger than an old-fashioned arm-chair, can be moved about from room to room, or be put where it will be both private and accessible. Nor will its presence poison the surrounding air, for there is no better disinfectant, no better deodorizer of organic refuse, than the dry earth contained in its hopper. Recognizing this property of earth, and also the laws of health, a wise Deity has, as the Creator, implanted in carnivorous animals the instinct of burying their excrement. As the great Lawgiver, he commanded the Jews to do the same thing. What cats and dogs do by instinct, man should do as well by reason as by divine command. Further: animal refuse thus treated becomes a rich and available manure. Like that fabled giant of ancient mythology, it gains strength and vigor from contact with its mother,—earth.

One thought more: As our title, *doctor*, indicates, we ought to be the teachers as well as the healers of the community,—the educators and the

refiners of those among whom our lot is cast. I once knew a member of our profession, a general scientist, and withal a great botanist, who so moulded the tastes of his fellow-townsmen that there is, I will venture to say, no other town in this country which, in proportion to the number of its inhabitants, contains so many excellent botanists, geologists, mineralogists, conchologists, and entomologists. Few farmers in that county have not had a liberal education, and scores there are who can show a well-arranged *hortus siccus* or give the botanical names of the indigenous plants and weeds. The town in which he lived has at this moment more successful schools—normal, public, and private—than any other of its size in the United States.

Now, what the late Dr. William Darlington did, each one of us can in a measure do, according to the talents vouchsafed to us. In scientific research, in the conflict of thought, our profession stands ever in the van. In that which refines, in that which uplifts soul and body, let it not lag behind. Begin, therefore, to teach as well as to heal; and the best lay-sermons you can at first preach are those against privies. Wage a successful crusade against these affronts to health and to decency, and you give better bone, better nerve, and better muscle to the state, and better morals to the people.

ORIGINAL COMMUNICATIONS.

YELLOW FEVER.

BY HARVEY L. BYRD, M.D.,

Professor of Diseases of Women and Children in the College of Physicians and Surgeons of Baltimore; President of the Epidemiological Association of Maryland, etc., etc.

Read before the Association by Appointment.

(Concluded from page 729.)

SYMPTOMS.

WE are, unfortunately, unable to present, as some authors have done, a regular order of symptoms as characterizing the initiation of the disease into the system. Much experience and close observation during three severe epidemics convince us that a *chill* is far from being the first or important symptom in the beginning of the disease. The paroxysm usually commences with a chilliness, but rarely is a well-pronounced rigor seen. The symptoms which usually usher in an invasion of this terrible malady may be defined *irregular;* varying in many cases with the circumstances of season, locality, constitution, age, and sex. We meet no such well-marked or sharply-defined symptoms as are almost always found in other forms of autumnal fevers; and it is only by careful examination of all the facts and circumstances in the commencement of an epidemic that the most experienced physician is enabled, in the beginning of an attack, to form a satisfactory conclusion in regard to the disease. A feeling of lassitude, a perverted taste or appetite, transient pains or uneasiness in the back and forehead, "cool streaks" down the back, often take the place of a chill, or even a general chilly feeling. To *these*, or the *chill*, heat and dryness of the skin soon succeed, with pains in the head, back, and limbs, and an uneasy feeling at the stomach. The *face is flushed*, the eyes red and muddy and appearing as though tears were about to flow; light is avoided, and in many cases the motions of the eye are painful. The patient looks alarmed, is anxious and restless when addressing you. The *pain in the forehead* (supra-orbital) is often intense, and always continues throughout the attack; confusion of intellect, or delirium, or even furious mania, is found from the first, in some cases. The *pain* and *aching* in the *back* are more or less severe, and occasionally almost insupportable. In the extremities the pains are usually severe, and invade both the joints and muscles of the legs, particularly the calf. The *stomach*, which Rush called the "throne of the disease," is almost invariably distressed and irritated, and vomiting is easily excited, or comes on spontaneously. First its contents are ejected, then bile, perhaps, and afterwards thin mucous fluid in large quantities and of different colors. The soreness and pain in the epigastrium are increased by retching; there is a sensation of heaviness and burning in the stomach, and the patient shrinks from pressure applied to that region. *Respiration* is slow or labored, with heavy, deep sighing, and præcordial oppression, or hurried, irregular, and embarrassed.

The *skin* is usually hot and dry, and imparts to the fingers a peculiar pungent sensation. The *orange hue*, so frequently alluded to by writers, tinges first the conjunctiva, then extends to the forehead, breast, arms, and body. It does not always manifest itself in the first stage of the disease, and may only be seen in the last, or it may not appear at all during life. It differs markedly, at least to the practised eye, from the yellow or sallow color of protracted intermittents and of jaundice, being deeper and darker, between a bronze and an orange color.

The *pulse* seldom exceeds 90, and is bounding, hard or jerking, sometimes irregular, and bears but little correspondence with the state of the general system. In some cases it is but slightly accelerated above the normal standard, and maintains remarkable uniformity, even in grave cases, until near the last. It is well calculated, therefore, to deceive the inexperienced, and to encourage hopes of recovery never to be realized.

The *tongue* is soft and swollen, so much so as to show indentations of the teeth, but it soon becomes fiery red at the point and edges.

The *thirst* is painfully urgent, and ice and cool drinks are vehemently demanded. In occasional cases, and during nearly the whole of an epidemic, the thirst was only moderately great: the above is, however, the rule.

The *bowels* are constipated, or torpid, and respond slowly to cathartics even of an active kind, and when moved the stools from the first are dark-colored and acrid.

Diarrhœa is of rare occurrence in the incipiency of the disease.

The *countenance* is so strikingly marked in expression in some epidemics as to enable an experienced observer to recognize the affection at a glance.

Even before the patient was aware that he was being attacked, we have often advised him to go home to bed, from observing this peculiar expression of the face as we passed him on the street. *The face is flushed and turgid, looking impatient, distressed, and gloomy; the eyes are watery and red; and in addition there is an unmistakable expression of fierceness and wildness of vision,* "resembling that of intoxication combined with sadness and terror." This is the best word-picture we can give of the peculiar "tout ensemble."

The foregoing symptoms constitute what has been not inappropriately named the "first stage of the disease," and form a sufficiently accurate description, as it is usually seen in our Southern cities, to enable it to be easily recognized. In this period is embraced the whole of the febrile stage of the disease in its ordinary course. It will be found to vary much in duration with circumstances, being longer or shorter even in persons of the same household. It sometimes extends to seventy-two, and may terminate within the short period of five, hours; but the average duration is from thirty-six to forty-eight hours.

The *second stage* is regarded as commencing when an abatement of several, or even of a few, of the leading symptoms of the first stage is observed, and when complete will form, not a remission as the term is applied in remitting fevers, but a total and perfect apyrexia. In this stage the yellow hue has extended to the whole surface of the body. The headache and pain in the limbs and back are absent, or greatly modified; the skin is soft; pulse natural, or but little more frequent and compressible than in health; less burning in the stomach; gastric irritability not so great; vomiting is diminished, and when it does occur is attended with less effort. The eyes are not so red and suffused; the flush of the face disappears, and the breathing becomes normal, or nearly so. This condition, so well calculated to deceive the patient, and even inexperienced physicians, into the belief that the worst has passed, if indeed convalescence has not actually begun, lasts usually from twelve to eighteen hours, and never longer than twenty to twenty-four hours; when the *third stage* may readily be known by the collapse which takes place, attended by extreme prostration of the patient. The orange hue of the skin grows deeper, and a bronze or mahogany appearance takes its place. This is particularly apparent on the face and hands. The pulse is quick, irregular, and depressed. The irritability of the stomach is now so great that nothing will be retained but for a moment, and its contents are ejected spasmodically and with force, the efforts being entirely involuntary and attended with little or no discomfort. The fluid thrown up at this time is seemingly a ropy, colorless mucus, which adheres closely to what it comes in contact with. This has received the names of "premonitory," "precursory," or "white vomit." The tongue is swollen, whitish, and moist on the sides, with dark-brown streaks in the centre. Sometimes it is dry and very red, and even cracked, so that dark blood is seen issuing from the fissures. *Hemorrhage* in some form, and from some surface of the body, if it has not already taken place, may soon be expected. Before its occurrence, the patient is cheerful and hopeful of recovery; but when it has unmistakably taken place, his hopes fade, and a marked change of countenance is again observed. The stomach becomes more and more irritable, and usually the first appearance of hemorrhage is seen in the ejected mucus, which constitutes what is known as *black vomit.* First the fluid thrown up is found mixed with dark-colored flakes, and these increase with the vomiting until the contents of the stomach seem to consist of a mixture of coffee-grounds and water. The fluid now escapes from the stomach even in hiccoughing, or spouts from the mouth as the patient lies on his back. The stomach often loses its contractile power at this time, and the fluid not escaping causes a peculiar gurgling, rumbling noise in that viscus, and in the bowels, attended with fulness and distention of the abdomen. In this condition, the intestines cease to be constipated, and discharge at an early period a fluid having the appearance and characteristics of black vomit. Breathing is laborious; the skin cold and clammy; great distress and oppression are experienced in the epigastric region; the patient sighs and moans; the eyes are dim and sunken; the tongue is tremulous and black; muttering and delirium ensue, and the powers of life rapidly give way. Hemorrhage may now take place from several sources, and thus hasten the end of the patient.

The foregoing symptoms have been related more nearly in the order of their occurrence under our own observation, and the arrangement adopted by Dr. Dickson, than by any other writer, and are as full and complete as our space will permit.

Yellow fever may, like other diseases, present an *inflammatory*—oftenest seen in the Southern cities—or *congestive* type; and the symptoms will be found to vary accordingly. *Cæteris paribus,* the congestive form is far more fatal, and more speedily so, than the inflammatory, and for reasons which must be sufficiently obvious to this scientific association: we shall not, therefore, consume time by further reference to them.

PROGNOSIS.

There are few diseases to which flesh is heir more fatal to life or more rapid in hastening their victims to the grave than yellow fever. Though the malignity and fatality are found to vary within wide limits in different localities, and in the same cities in different years, the prognosis may be generally regarded as unfavorable. The mortality has in certain cities reached as high as ninety per cent. in a particular epidemic, and fallen in other places as low as four to five per cent. It is a disease, however, that always requires the utmost vigilance and care of the practitioner for its successful management. The prognosis in individual cases will necessarily be greatly modified by circumstances. Apart from the importance of careful consideration of constitution,

age, habits of life, etc., in every case, the stomach should never be overlooked or neglected. Indeed, careful attention to its condition is of paramount importance if a successful issue is to be reached. It will be readily seen that its tranquillity and ability to retain what is directed to it are vitally important in the treatment of the disease. Uncontrollable vomiting is almost necessarily fatal. A "dark or sub-livid color of the tongue," darkness under the eyes, suppression of urine, and a considerable irritation of the urethra, particularly towards the glans, forcing the patient to squeeze the penis, as happens in stone or gravel, are symptoms of the utmost gravity, and portend a fatal termination of the disease. We have witnessed suppression of urine in yellow fever and cholera, and seldom has recovery succeeded it in either affection. There are other points of importance in this connection which might be profitably mentioned were time afforded; but the standard authorities are accessible to all, and we hasten to say a few words on the *pathology* of yellow fever. Attention has already been directed to its germinal or fungoid origin, and the circumstances necessary to the development of these germs in the human body in the production of the disease. But little, therefore, remains to be added beyond the fact that they alter or change the character and constituents of the blood in a most astonishing and extraordinary manner, increasing its fluidity and devitalizing it to such an extent as to render it unsuited to the proper nutrition of the tissues and organs of the body, and prone to escape by exosmosis or otherwise from various surfaces, internal or external, or from both, under certain circumstances, in the form of *hemorrhage*.

Pathological changes have been found on dissection of the body in various organs and tissues; but the most constant alterations or lesions occur in the blood, stomach, heart, brain, liver, and skin, the orange color of the latter being of more constant occurrence than any other except the abnormal condition of the blood. Indeed, it may be safely asserted, without the fear of contradiction or satisfactory refutation, that this most important *fluid is always disorganized. Black vomit* is the diseased *blood* still further *changed in character and appearance by the fluids which it encounters on entering the stomach*, and is nothing more and nothing less, as both chemical and microscopic analyses have satisfactorily proven. The precise manner of its taking place is probably by *diapedesis*. The liver, to which so much attention has been directed by some authors, presents no uniform appearance or condition. It may be found natural in appearance, or filled with dark blood, or flabby and soft. The "box-wood" or "straw color," or "café au lait" or "fawn color," as this appearance has been denominated by different writers, is far from being of very frequent occurrence, and is by no means so constant as has been supposed by some authors. But it is proper to state that, if it is not *peculiar* to yellow fever, it is often found present in persons who have died of that disease. Subcutaneous effusion of blood, or extensive ecchymosis, is seen in hemorrhagic cases.

TREATMENT.

It would be impracticable to attempt an enumeration of all the remedies, and the effects attributed to them by various writers, which have been employed in the treatment of yellow fever. In fact, almost every article of our voluminous materia medica has been recommended at one time or another, and more or less extolled for its real or imaginary therapeutic properties in this disease. *Our* remedies are not numerous, and are selected and administered with reference to the particular *stage* of the fever and *condition* and *age* of the patient. When these important considerations receive due weight, the treatment of yellow fever in our hands has not been unsatisfactory, as we remember the rapid course it is prone to run. It is not often that a case is seen in general practice in the forming stage, or that we witness a chill when it occurs; and we will therefore proceed to direct attention to some of the more important remedies in the *first stage*. As the disease has, under our observation, generally partaken of the *inflammatory* type, our treatment was directed with a view to combat the most urgent and important symptoms. As a rule, calomel, alone, or in combination with rhubarb and chalk, magnesia, or charcoal, and a small portion of pulverized capsicum, was the dose first administered, and this was followed, in two hours at farthest, by one of the neutral salts. If the bowels did not respond in a reasonable time, two or three pints of tepid water in which were dissolved one or two tablespoonfuls of common salt (chloride of sodium) were pumped gently into the bowels. In rare cases the lancet was used before any other remedy; as a rule, however, it was inadmissible, and then cold water was resorted to, by sponging, pouring, or shower-bath. This last method, when the appliances were at hand, was found peculiarly efficacious in relieving the excruciating head-symptoms, and the congestion of the eyes and face, as well as the heat of surface, particularly if the patient's feet were at the same time placed in warm water impregnated with mustard or nitro-muriatic acid, so as to produce a tingling on the surface. Broken ice swallowed instead of water was grateful and beneficial. If the head-symptoms returned with violence, the hair was cut, ice applied to the head, and warm bottles or bricks to the feet. Inhalations of ammonia and chloroform were used for the same purpose. On the slightest evidence of relaxation of the skin, and sometimes before its occurrence, recourse was had to the vapor bath, or even warm mustard bath, with the object of establishing diaphoresis. Mustard, dry cups, or chloroform over the stomach not only contributed to the relief of the pain in that organ, but assisted in keeping it quiet, a matter of vast, of paramount importance in all cases of yellow fever. Tincture of aconite root in a mixture of mint-, cinnamon-, or orange-flower-water, with bicarbonate of potash, is a combination of value in the final stage, and may be continued with benefit, if the aconite be omitted, in many cases in the second stage.

From two to four drops of aconite, and two to three grains of bicarbonate of potash, in a dessert-

spoonful of orange-, mint-, or cinnamon-water, as most agreeable to the patient, were given at intervals of two hours, after the bowels were moved, until the pulse was reduced and the skin became soft or moist. Hypodermic injections of veratrum viride, in highly inflammatory cases, were used with benefit in a few instances. *Muriated tincture of iron*, suggested by us in consultation with Dr. R. D. Arnold in a desperate case (Master Yates Thompson) in Savannah,—and from its charming effects in that instance grew its notoriety in that city during the terrible epidemic of 1854,—is a remedy of great and acknowledged efficacy in the treatment of many cases of the disease.

Second stage.—Prostration is clearly manifest in this stage; and it requires constant vigilance and attention to tide the patient safely over it.

Nitrate of silver in conjunction with hyoscyamus or opium, and acetate of lead, either alone or with opium, and muriated tincture of iron, should be resorted to, and the careful use of stimulants now begun and continued more or less energetically to and through the third stage. The patient should be sustained in every possible way in this trying stage, both by nourishment and remedies, and nature aided, as far as can be done, to regain her lost powers.

The recumbent or horizontal position should be preserved from the beginning of the second stage until the establishment of convalescence. Attention directed strictly to this one point is of the greatest importance in the successful management of yellow fever.

EFFECTS OF AN ATTACK ON THE SYSTEM.

On recovering from an attack of yellow fever, the individual will be found protected against a subsequent invasion of the disease, and the immunity will be almost complete if his residence is continued within the yellow-fever zone. *Acclimation* against zymotic diseases, as intermittent and remittent fever, etc., and the curing of previously existing chronic affections, such as rheumatism, neuralgia, certain cutaneous diseases, etc., are often observed as results of an attack of yellow fever. In some persons a tendency to obesity or the accumulation of adipose tissue is found to take place on recovery from the disease.

The length to which this paper has extended admonishes us that it should be brought to a close as speedily as practicable. Hence we beg to refer this attentive and appreciative audience, for additional and valuable information on this important subject, to the writings of some of our distinguished countrymen, as Lining, Irvine, Hosac, Wistar, the good, the great, and the lamented Rush, *clarum et venerabile nomen*, La Roche, Nott, Fenner, Dowler, North, Hume, and many others, and last, though by no means least, the eloquent and accomplished Samuel Henry Dickson. In naming the above it is no part of our wish or purpose to make invidious distinction between our confrères who have so ably written upon, and gallantly combated, yellow fever, but to pay a passing tribute to the noble dead. One word more of the departed Dickson,—and we would place the feeble tribute on his newly-made grave:—his eloquence was the legitimate offspring of purity and earnestness, and around the massive shaft of his logic the light of enthusiasm plays like sunbeams around the statue of Memnon.

We have presented as many facts appertaining to our subject as time would allow, believing that "*truth* never shrinks from a fair encounter." In the words of Milton, "Truth is strong next to the Almighty," and doubtless "is the purest ray reflected from the brightest gem in the diadem of the Great Jehovah."

366 North Fremont Street, Baltimore, Md.

NOTE ON THE USE OF INJECTIONS OF SOLUTION OF BROMIDE OF POTASSIUM IN CHOLERA-COLLAPSE.

BY WILLIAM PEPPER, M.D.

IN a brief article published in these columns (July 12) I suggested the use of injections of warm solutions of bromide of potassium into the veins of patients suffering from cholera-collapse. I am indebted to Dr. Joseph G. Richardson for calling attention, in the issue of July 26, to the fact that the solution recommended (gr. xv to f℥j) was evidently too strong; and I am glad to take this opportunity of correcting an error which was inadvertently published. It is, indeed, to be remembered that we cannot anticipate that the injection of a small quantity of a three per cent. saline solution into the veins of a cholera patient will produce effects upon the blood at all comparable with those which are seen to follow when blood-corpuscles are treated with it under the field of the microscope. The fluid becomes diluted with the serum of the blood in the very act of injection; and it is further probable that the action of such saline solution upon the corpuscles of the thickened blood in cholera would be less powerful than normal.

It is, however, very possible that a three per cent. solution would produce some injurious action upon the corpuscles; but what is more certain is that the quantity of fluid injected should be quite considerable. I would recommend that from one to one and a half pints of water (of a temperature of 105° Fahrenheit), containing fifty to seventy-five grains of bromide of potassium in solution, should be used at each injection. The employment of a large amount of fluid is evidently of great importance, since one of the beneficial results of such injections is undoubtedly the dilution of the thickening blood. It has also been a matter of uniform experience that the injections should be of quite high temperature (105° to 108° Fahrenheit),—a fact which Dr. George Johnson explains by supposing that the warmth relaxes the spasm of the minute arteries.

Dr. Hanot recently reported to the *Société de Biologie* in Paris a case in which uræmia, supervening on general paralysis, was diagnosed by the symptom pointed out by Bourneville,—a rapid and general decline of temperature.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

CLINIC OF DR. H. C. WOOD, JR., ON DISEASES OF THE NERVOUS SYSTEM.

Reported by L. B. Baldwin.

TRIGEMINAL NEURALGIA.

MARGARET COLLIGAN, æt. 60 years, Irish, married, mother of eight children; family history, healthy,—*i.e.*, no neural disease.

Six months ago, noticed something the matter with her right eye,—"pain and watering." For this she visited the Eye Dispensary in Locust Street, but after a few visits had to give up, on account of the severity of the weather. About the 1st of March, began to have pain in face and head,—right side,—gradually increasing in severity up to the present time. Shortly after this, began to have a buzzing in the head. Ascribes all her troubles to an attack of rheumatism which confined her to her bed for five months previous to the beginning of her present affection.

Present condition.—Appetite, digestion, and secretions natural.

Has a steady aching pain upon right side of head and face, extending almost as far back as the occiput and forward to the median line of face; felt also beneath jaw and at root of tongue.

There are paroxysms at irregular intervals throughout the day, during which the pain becomes sharp and lancinating, the muscles of the face at the same time contracting, principally the orbicularis palpebrarum and zygomatici,—"making faces." There is no anæsthesia; no appreciable paralysis; pain upon pressure over the infra-orbital and mental foramina; none over supra-orbital.

The right eye is partially closed; conjunctiva reddened and watery. There is a continual running from the right nostril; complains of a constant buzzing or singing in the head, likened to the noise made by a running hydrant; tapping with the fingers over temporal region causes no pain, but a noise as of thunder is heard by her; complains at times of a deep-seated pain in eyeball.

Symptoms all increased in severity at night.

The first feature, gentlemen, which attracts attention in the case before us is the intense pain which she suffers on one side of the head without any inflammation or other obvious cause. The points of most intense and limited pain are found to be over the infra-orbital, nasal, parietal, and lingual branches of the trigeminus; most severe in the parietal region. Attention was called to the neuralgic foci in these complaints by Valleix, who found them to correspond to points at which the nerves make their exit from bony foramina; and we find patients suffering with intense pain at one or more of these foci, which, according to its situation and cause, receives different titles for purposes of distinction and classification.

Neuralgia of the trigeminal nerve is a common and serious disease; serious not so much by threatening life as by causing intense suffering and rendering life a burden.

Most authors present for consideration six different forms. I think, myself, five only exist, as I shall endeavor to show you that "clavus" and "migraine" are identical in origin and in symptoms and require the same treatment.

The first form, known as "*rheumatic*," is quite common. It occurs in persons subject to rheumatic troubles, or it may be traced directly to exposure to cold or wet.

In my experience, the localization of pain to foci is not so marked in this as in other forms of trigeminal neuralgia; and by the acuteness of the attack and the history of its cause, or by the known diathesis of the patient, you may in most cases readily recognize this variety.

The second form is the *malarial*. It is very important that you should be able to recognize this variety, because its treatment is definite and both rapid and certain in results. It occurs in those who have been exposed to malarial influences; and with it other forms of malarial disease may or may not coexist or alternate. Its characteristic phenomena are paroxysms of intense pain, almost always confined to the supra-orbital focus, and occurring at regular intervals. It may assume the quotidian, tertian, or quartan type. It may be the first symptom of malarial disease, or it may plague the victim of the most chronic malarial fevers.

The diagnosis is confirmed by the results of treatment with quinia. This alkaloid must not be given in doses of gr. xv daily, as in simple *ague*, but in doses of gr. xxx daily; and although temporary deafness and even blindness may be produced, you will cure your patient.

Migraine is the affection popularly known as "sick headache," or rather it is one of the affections so known, for there is another sick headache, commencing with dizziness and blindness, in which the pain is a heavy, dull ache extending clear across the forehead, and is in reality dependent upon digestive derangement. In migraine this is not so. The pain occurs in paroxysms at irregular intervals, is unilateral, and especially affects the supra-orbital focus. It sometimes comes on suddenly, more generally, however, gradually, and increases steadily until it amounts to agony. Sick stomach is generally developed, and after it the pain subsides in most cases, but sometimes violent repeated vomiting, with intense agonizing headache, will persist for hours. That the vomiting does not really relieve the pain in those cases in which it appears to do so, and that the symptoms are not really of gastric origin, are shown by the facts that, when artificially produced, emesis does no good; that it often fails to relieve even when spontaneous, and that in many attacks it is absent. It merely corresponds to the period of lowest depression, when the system is about to react.

Migraine always develops itself about the age of puberty, and is generally hereditary. Some debilitating influence is usually the immediate cause; but this alone is seldom sufficient to produce the disease unless there is a hereditary predisposition; on inquiry, a brother, sister, and father are often found to have suffered from some neurosis,—not *necessarily* the same form of nervous disorder, for hysteria or epilepsy in one generation may be followed by migraine in the next.

I may say, here, that I have seen migraine occurring in families heavily tainted with hereditary gout, and believe that in some cases it is simply a form of "irregular" or "nervous gout."

As an example of the points above alluded to, I may mention the case of a lady whom I attended in private practice, in whom, at the age of seventeen, acute diarrhœa was converted into a chronic one by the skilful ministration of an intelligent homœopath, and in whom during the state of induced debility migraine of a very severe type developed itself.

In *clavus* the pain is more limited than in migraine to a simple focus, very generally to one of the parietal. The affection, indeed, gets its name from the exceedingly local character of the pain. By the point of your finger you can cover the affected spot; and, as the agony is often compared by the sufferer to the feeling of a nail being driven into the head, the term *clavus*, a nail, has been applied to it. Like migraine, clavus is first seen in early life, and in later years may degenerate into attacks of neuralgia having no specific type.

What is the difference between its course and that of migraine? You have the same character of pain, nausea, sick stomach, vomiting, with or without relief of the paroxysm; the same hereditary influences exist in both; neither occurs for the first time in old age. When a neuralgia develops after the age of fifty, you may say positively it is neither clavus nor migraine.

Clavus is, then, a trigeminal neuralgia of the same form as migraine; and as it sometimes alternates with migraine, I do not think that they ought to be considered distinct affections.

Clavus is sometimes called hysterical. This is probably an error, for if it does occur with hysteria it is in no wise essentially connected with it. Perhaps the best way of expressing the truth would be to say that, whilst there may be a hysterical clavus, clavus is not necessarily hysterical.

The fourth form of trigeminal neuralgia is *tic douloureux*. This is more serious than clavus or migraine. It is very often incurable, and renders the patient miserable for the remainder of his days. This form, contrary to migraine, never develops in early life, but during middle age and at later periods, when the various tissues are losing their vitality. Nearly always evidence of atheromatous disease may be discovered by the tortuous course and hard, thickened character of the arteries, by the "arcus senilis," or by the loud, clanging second sound of the heart, betokening aortic change. It sometimes involves the branches of the trigeminal which accompany the trifacial, and thereby gave origin to the old belief that that nerve was sometimes sensory. It consists of attacks of agonizing pain occurring suddenly and ceasing as suddenly, in half a minute or so, and again returning until the attack which is composed of these "tics" is over, to return probably in five or ten minutes.

The muscles of the face often twitch, or are violently convulsed, during the attacks; but in some cases of tic they become set and rigid during the paroxysm, whilst in others they are not evidently affected. These attacks are sometimes relieved by *firm* pressure, but often are produced by a slight touch.

An affection which you may confound with trigeminal neuralgia is the so-called *anæsthesia dolorosa*. This disease at first sight seems very peculiar or paradoxical, from the fact that sensation is entirely lost at the points to which intense pain is referred, so that you may cut or burn the side of the face affected without producing pain. The intense suffering and the sensory paralysis are due to some lesion at or near the origin of the nerve. A tumor, for instance, may so press upon the trunk close to its origin as to destroy its power of conducting impulses from the periphery to the centre, whilst by a simple reflex irritation, or by a propagated neuritis, the centre may be thrown into a condition of high excitement. The resulting pain is of central origin, but is referred by the patient to the peripheral ends of the nerve, owing to the long-established habit of the part, and is strictly comparable to the pain which is felt in an amputated limb. Anæsthesia dolorosa is to be distinguished from true neuralgia by the presence of the anæsthesia which its name indicates.

You will now, I hope, be better able to interpret the symptoms of the patient before you, whose history I have read. The case, in its coming on late in life, in the obstinacy of its attack, and in the coexistence of evidences of degenerative changes in the tissues, undoubtedly resembles one of tic douloureux; but the history of chronic rheumatic trouble preceding it, and the fact that she has improved under treatment for the rheumatic form, induces me to call it *rheumatic*. Neither do you find the pain so moderate in "tic" as presented in this case.

Let me call your attention, gentlemen, for a moment, to this patient's eye. You see that there are very distinct evidences of structural alterations. Not being an oculist, I do not offer any opinion as to their nature, but simply show them as instances of the trophic changes which not rarely accompany, if they are not indeed due to, trigeminal neuralgia.

In the case of migraine to which I have alluded, the attacks were often referable to a direct cause: certain states of the weather or degrees of atmospheric moisture would at times bring them on, and overfatigue would always have the same result. In this lady I have often noticed a fetid odor of the breath preceding an attack, especially when the latter was produced by over-fatigue from any cause. Thus, a long walk, or inordinate household duties, would in a twinkling, as it were, cause a perfectly sweet breath to become a very offensive one. The odor disappeared as the attacks subsided, and any gold about her person became blackened or tarnished at such times, showing the presence in the perspiration, as well as in the breath, of hydrogen sulphide, or other sulphur compound. We find in some cases of migraine peculiar alterations in the modifications and appendages of the skin. The hair, for instance, becomes hypertrophied, or, *vice versâ*, atrophied; and a portion or all of the hair may lose its color. In the case of Dr. Anstie, who suffers from this disease, a few locks of his hair become white during each attack, and again regain their color.

As in intercostal neuralgia we may have herpetic sores along the course of the intercostal nerves, in migraine we have various eruptions. Thus, the case already referred to suffers from acne almost exclusively confined to the side of the face in which the neuralgia is seated.

The treatment of trigeminal neuralgia necessarily varies with the form. In migraine or clavus the indications are to relieve any existing disorder that may be connected with it, and build up and improve the patient's general condition. The case of migraine here described was treated for chronic diarrhœa, and by hygienic measures, for a time, without any direct efforts being made against the neuralgia, and the attacks were soon reduced from four or five a week to one a month.

For those persons who naturally have a dislike for fatty, oily matters, and where there are no dyspeptic symptoms, cod-liver oil is often of great advantage.

We must be careful in using alcohol and opium in full doses for the relief of pain, for fear of producing the habits of intoxication and opium-eating. Opium you will find to disagree with many of these cases of migraine, causing great nausea and vomiting, which last for twenty-four hours. I have obtained great relief from a combination of opium and the bromides in such cases: for instance, tinct. opii deod., ℥ xxiv, with potass. brom., ʒss, may enable you to give ease without bad results.

In rheumatic trigeminal neuralgia, of which this patient is a specimen, I employ repeated blisters over the mastoid region, with the internal administration of potass. iodid. Tincture of aconite, or other anodynes, may be used externally, or opium internally, if necessary, to relieve pain.

Where you have facilities, the employment of sulphur- and vapor-baths should not be neglected.

There is a syphilitic form of this disease, probably dependent upon the pressure of thickened periosteum on the nerve as it passes through its bony foramen. This yields readily to potass. iodid. and counter-irritation.

[The patient rapidly improved under the use of the iodide and the local application of blisters. In a few weeks she was discharged, well.—H. C. W., Jr.]

BELLEVUE HOSPITAL, NEW YORK.

OPIUM-POISONING—ADMINISTRATION OF OXYGEN—DOUBLE PNEUMONIA—DEATH.

BY W. H. FARRINGTON, M.D.

THE following are the notes of a case of opium-poisoning, the first, so far as I know, in which oxygen has been employed.

Patient, V. P., æt. 25, drug-clerk; took by mistake sol. morph. sulph. (Magendie) ʒiij on the morning of April 16, 1873, about 7.30 A.M. When seen a few minutes later, he was rapidly becoming comatose. A physician was immediately summoned. The patient now was fully comatose, his pupils intensely contracted. A hypodermic injection of atropiæ sulphat., gr. $\frac{1}{30}$, was given, and an enema of coffee. From the ambulance surgeon he received brandy, and efforts were made to arouse him by flagellation. On admission (10.40 A.M.), patient was completely comatose, with entire absence of reflex sensibility. The surface was cold, the features dusky, the lips and finger-nails cyanotic. Pulse 56, feeble and irregular. Respiration 13, noisy, shallow, and irregular. Pupils were fully dilated and irresponsive. An enema of coffee and whisky was given, and artificial respiration made by Sylvester's method, until 11 A.M., when a galvano-faradic battery was obtained. The secondary current was administered, one pole placed over the course of the phrenic nerves in the neck, the other over the anterior origin of the diaphragm. His condition slowly improved, and at 12.15 P.M., though still unconscious, the surface was warm, the respiration more profound, but slow, the pulse 112, full, compressible. Cyanosis had disappeared. At 1.30 P.M. the battery began to fail, and almost immediately the pulse sank, and in a few minutes could not be detected at the wrist. Cyanosis returned; the respiration again became superficial. A hypodermic of whisky, ♏xxx, was given, and subsequently of atropiæ sulph., gr. $\frac{1}{30}$. A second battery was obtained, and the bad symptoms again disappeared. In an hour this battery also failed, and a repetition of the above took place. A third battery was kept in operation until 5 P.M., when a jar of oxygen was obtained. The patient was still comatose, insusceptible to external impressions. Respiration slow, 12, but good. The gas was administered by means of a dentist's "laughing-gas" bag, care being taken to admit some atmospheric air. During its administration some evidence of returning consciousness was manifested, the patient opening his eyelids and looking around vacantly, immediately relapsing into coma when the bag was removed. A second bagful was given, with a similar effect. A third bagful was administered, and the patient became still more conscious, the action of the gas being assisted by flagellation. A cupful of coffee was swallowed, and the patient was walked up and down the ward. By these means he was kept awake until 7 P.M., when, though still drowsy, he was able to converse intelligently. Symptoms of pneumonia of the lower left lobe manifested themselves next day, and in a week from the day of admission the patient died of double pneumonia. This could not possibly have arisen in consequence of exposure, as the greatest care was taken to avoid currents of air. Notwithstanding the fatal termination of the case, I am fully convinced of the utility of the gas in cases of this sort.

FISTULA IN ANO.—Dr. Hute employs an ethereal solution of iodine in fistula in ano, which is more exciting than the tincture. Patients are not obliged to keep their beds. He has had several cures after one injection.—*Medical and Surgical Reporter.*

TRANSLATIONS.

DETERMINATION OF UREA.

Translated from *Le Mouvement Médical*, June 7, 1873.

AT one of the last séances of the Society of Biology at Paris, M. Esbach related his experience in endeavoring to discover whether the previous decolorization of urine by animal charcoal would facilitate the determination of the proportion of urea. The results of his experiment are as follows:

Decolorized urine submitted to a ureometric analysis shows a sensible loss of about one-tenth of the nitrogen which should normally exist. In acting separately on the decomposable nitrogenous elements with the hypobromite of soda, it is found that there is a marked loss in the solutions of urea and creatin, but none in that of uric acid. Finally, examining the proportions of these different elements in the urine, M. Esbach established that in decolorizing urine by animal charcoal there would be an error of from two to five grains in the urea contained in the urine of twenty-four hours.

It is known that the hypobromite of soda disengages instantly all the nitrogen of urea; but it is not so with the other nitrogenized substances in urine, such as creatin, creatinin, and uric acid. These compounds only give up their nitrogen by successive transportations in such a manner that by prolonging the action of the reagent one can always proceed with their decomposition.

Now, M. Esbach has found that he only determines $\frac{1}{20}$ of the nitrogen in uric acid, $\frac{1}{10}$ of that in creatinin, and $\frac{2}{3}$ of that in creatin; and after the necessary calculations he concluded that by his method the greatest error caused by other substances than urea is $\frac{1}{70}$, an error which he considers to be practically unimportant.

M. Esbach at first thought to determine as a whole the nitrogenous products of animal waste, but now recognizes that he can scarcely determine the *urea;* and it is this important result which he wishes to make known.

HYPODERMIC INJECTIONS OF NITRITE OF AMYL IN CHOLERA.—Dr. David B. Smith (*Indian Medical Gazette*, May 1, 1873) reports a case of cholera-collapse treated with nitrite of amyl administered hypodermically. Two drachms of the drug were thus given in one hour and thirty-six minutes. Respiration was slightly accelerated, the temperature rose two degrees, the effect on the pulse was transient and insignificant, and the general condition of the patient was not in any way improved. Death ensued two hours and a half after the operation, which had caused slight restlessness, but neither thirst, dyspnœa, nor convulsions. According to Dr. Talfourd Jones, there are the following theoretical reasons for the employment of amyl in such cases:

1. The collapse of cholera is the result of an impediment to the circulation of blood through the lungs, and this impediment is due to the contraction of the muscular fibres of the minute pulmonary arteries.

2. The cramps of cholera are due to a like spasm or contraction of voluntary and involuntary muscular fibre in other parts of the body.

3. Nitrite of amyl possesses the property, when taken into the system, of causing relaxation of muscular spasm and arterial dilatation.

4. In many features there is a considerable resemblance between cholera-collapse and asthmatic collapse.

5. Nitrite of amyl is a remedy capable of giving instant relief in asthmatic collapse.

In the above case, the remedy had a very careful and fair trial, caused no unfavorable symptoms, but certainly could not be said to have produced any beneficial effect whatever.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 23, 1873.

EDITORIAL.

PRIVIES AND MORALS.

"GIVE us an ounce of civet, good apothecary, to sweeten our imaginations," was our cry after reading the lecture which heads this number of our journal. But to be in harmony with the facts and requirements of the day, repulsive though they sometimes may be, should be the higher aim of the physician,—"to teach as well as to heal." From confining his remarks, however, to the diseases of women, Dr. Goodell could not, necessarily, grasp the subject in its fulness; and this has led us to choose his lecture as the text of this editorial. For if the evils arising from the present system of closets are so many and so grave when seen from a single point of view, what must they not in the aggregate sum up?

The study of excrementitious products, unless under the ægis of palæontology, has too long been excluded from the pale of science. But the time has come when coprolites must yield in interest to what naturalists would call the "wet specimen." For the former is merely an evidence of past life; the latter menaces life; and life, according to the Roman, is not simply *to be*, but *to be well*. The subject of closets, therefore, is one which should enlist the earnest attention of every hygienist; not one to be monopolized by itinerant agents and the vendors of royalties.

What to do with the sewage of a large city is a very grave question; a problem still practically unsolved. As matters now stand, the ground over which we live and move and have our being is honeycombed by cesspools, burrowed by drains, and sodden with fæcal matter. We dwell in the valley of the shadow of death, with apparently no way of escape. The privy is a pest-breeder which we trust a progressive intelligence will not long tolerate. The evils let loose from this box of Pandora are too well known to need comment. Whole towns have been infected by its malignant germs, great cities decimated by its putrid percolations. The water-closet offers so much privacy, so many comforts and conveniences, that it will long maintain a strong hold on the public favor. But, apart from other hygienic defects, it threatens to pollute our rivers, and, therefore, to poison our only sources for an unlimited supply of water. Again, it compels the loss of a most valuable manure, which should be reclaimed for the truck farms lying around a great city. In this dilemma, the only *tertium quid* which science can offer is the earth-closet; and this, with all its imperfections, we must accept until something better "turns up."

The want of accessible closet-accommodations is another evil felt throughout the length and breadth of this land. Although the lecturer has enlarged on this point, yet he has neglected to advert to the lack, in cities, of public closets. What one of our readers in his round of visits has not been at times so "straitened in his bowels" as to suffer unspeakable agony both of body and mind? Women from the country who visit the city "on shopping thoughts intent," have absolutely no places where they can relieve themselves. The only ones generally available to the other sex are such filthy apologies as are to be found in low taverns and drinking-shops. Women, therefore, are made constantly liable to all those disorders arising from over-distention; while men have thrown in their way an additional temptation to intemperance. With these facts staring him in the face, can no philanthropist see it in the line of duty to become the Tancred of a public-closet movement, the Coryphæus of a new municipal departure?

In these advanced times, when the moral differences between the sexes are in danger of obliteration, when strong-mindedness aims to become a virtue, and when foreign manners—or rather want of manners—are held up as examples, there may be some who will stamp as sentimental rhodomontade the encomiums of the lecturer on the so-called "prudery" and "false modesty" of our women. But we put it to those of our readers who have buckled on knapsack and footed it through the less beaten paths of European travel, whether they have

not often seen such instances of shameless exposure as they would not tolerate in their own countrywomen. From a painful experience we know that very few of the hamlets and villages possess even the semblance of a privy. The adjacent fields and highways tell plainly to the sight and smell the approach to human habitations. The way through the streets themselves has to be very cautiously picked even in broad daylight. The mortifying surprises—at least mortifying to the ingenuous tourist—are unpleasantly frequent. One soon becomes "disillusioned" and "disoriented." Even where proper accommodations exist, decorum and decency do not. To give but a single illustration: While staying at one of the hotels in Venice, we one morning suddenly came upon a lady who was worshipping with unclosed portals in the temple of Cloacina. We blushed; but she, not a whit abashed, kept up a lively chat with a party of one lady and two gentlemen who were without, awaiting their turn.

Of course, except in a Garden of Eden, such absence of shame goes hand-in-glove with license of language and of morals. Human nature being human nature, they are of necessity inseparables. Witness the licentious tone of the best French novels, the broad jokes and double-entendres still tolerated by foreign society, and the utter lack of respectful deference to woman which characterizes the people of continental Europe. More than a hundred years ago, a French lady somewhat confused the not over-bashful author of the "Sentimental Journey" by using the language of the nursery to explain her short absence from the coach in which they happened to be fellow-passengers. This artlessness still thrives luxuriantly on Gallic soil. May it never take root in our own!

DISPOSAL OF THE SEWAGE IN PARIS.

FROM the *Medical Times and Gazette* for July 12 we glean some facts most interesting to hygienists and agriculturists. The drainage of Paris is to be prevented from entering the Seine, and to be utilized by being received into two vast "collecteurs," one on each river-bank. Thus far the experiment, although uncompleted, has worked to a marvel. A vast tract of sandy land, close by the gates of the city, and known as the plain of Gennevilliers, has long been proverbial for its sterility; but, by being flooded with the sewage-water, it has been converted literally into a most wonderfully fertile garden. Asparagus there now attains perfection in less than two years. Beet-roots reach the weight of from twenty to thirty-five pounds. Artichokes, cabbages, lettuce, and rhubarb grow to a colossal size. As to fruit-trees, they bear beyond all precedent. The annual rents, says the *Revue des Deux Mondes* for July 1, have consequently risen from eighty to six hundred francs per hectare. In two or three years the whole sewage of the city will be diverted from the Seine to the two thousand hectares of this sandy plain. As soon as this has been accomplished, every private house will be made to communicate with the sewers, and the lumbering night-carts, with their noisome stenches, will soon be among the things that are not in that gay city. To give some idea of the magnitude of the undertaking, there are at the present time in Paris 85,775 *fosses d'aisance*, of which 52,128 give employment to several hundred night-men.

CORRESPONDENCE.

To the Editor of the Philadelphia Medical Times:

DEAR SIR,—I have read with much interest the letter of Dr. Julio J. Lamadrid, in your journal of August 2, in regard to a fistulous opening over the sacrum, containing hair. Dr. J. Mason Warren, in his "Surgical Observations," refers to several of these cases, and adds some remarks, which I here quote, in regard to the nature and origin of the disease:

"On opening this fistula in similar cases, a small curl of hair has generally been found occupying the bottom of the cul-de-sac. This hair seems occasionally to act as a foreign body, giving rise to inflammation, with the formation of abscess, resulting in fistulous openings extending in various directions, thus often concealing the original difficulty. By a careful exploratory operation, however, the little wisp of hair may be discovered in some part of the sinus, lying perfectly loose and unattached to the surrounding tissues. I have once seen this in a woman whose hair was dark and more than usually developed in that region; all the other cases, numbering perhaps eight or ten, have been men.

"The origin of this singular affection is involved in obscurity. It would seem possible, however, that it may begin in the stout hair or hairs arising from a single follicle becoming in some way diverted from their normal direction and inverted upon themselves within the follicle itself; the continued growth of the hair would then result in the formation of a tangled knot or ball of hair, which might readily give rise, after a time, to irritation, just as a similar accumulation of sebaceous matter in the follicles of the face may excite that form of inflammatory action known as acne.

"The occurrence of the disease in the median line between the folds of the nates may perhaps be explained by the constant pressure and moisture of the part, softening both the newly-formed hair and the epidermic cells surrounding the mouth of the follicle.

"The treatment of this affection consists in laying freely open the cavity or cavities when the occurrence of inflammation has involved the skin and subcutaneous tissue; or, in case the skin still remains healthy, the sac may be laid open and then dissected out. The integuments should be brought together with one or two sutures, thus insuring a more speedy cure than if a simple incision is practised. This affection is interesting in connection with what has just preceded it, from the fact that the persons who apply for relief almost always suppose that they are laboring under the disease of fistula in ano."

I do not remember to have seen an account of this disease in any other work on surgery.

I am very respectfully yours,

J. Collins Warren.

Boston, August 4, 1873.

To the Editor of the Philadelphia Medical Times:

DEAR SIR,—Some time since, I had under my observation in a hospital a medico-legal case in which I was much interested, as the anatomical relations of the wound were curious, and a knowledge of the extent of the internal injuries would have been valuable by enabling me in the future to make a more certain diagnosis in similar cases. The patient, after lingering some time, died, and was straightway removed from the hospital. The coroner's physician made an examination, and discovered—something; what, I only know from the scientific description of a newspaper reporter. Now, my complaint is that no one connected with the treatment of the case had an opportunity to be present at the post-mortem, either to verify or correct the diagnosis made during the patient's life.

The case was one which might have been of interest to report could it have been given in its entirety; but now it is lost, with the treatment locked up in one place, and the post-mortem results buried in the depths of the mind of the coroner's physician. I say buried, because the medical profession rarely derives information from the scientific experience of that official in this country.

It seems wrong that a hospital should care for a patient while living, and its staff be robbed of any possible pathological information when he is dead,—their only remuneration.

If our large cities were districted, and the coroner's necropsies performed in the dead-rooms of the various hospitals, valuable information might be furnished to students which could be derived from no other source. If this is impracticable, and the autopsies must be made at the morgues, why should not the coroner's physician deliver a course of lectures and demonstrations, as was done by Caspar, and save some of the material which is now utterly wasted? In either case, it would be only civil to invite those to be present at the post-mortem who have been interested in the case during life, and who will in all probability be obliged to waste time by dangling round the courts as witnesses.

Yours,

Hospital.

REVIEWS AND BOOK NOTICES.

Contributions to Practical Surgery. By George W. Norris, M.D. 8vo, pp. 318. Lindsay & Blakiston, Philadelphia, 1873.

It is a good custom which leads men at the close of their professional career to lay before the public some of the results of their experience. With us such books always carry weight, knowing their conclusions to be based upon the observation of more than one or two cases, differing widely from so many of the medical publications of the day, which, founded upon defective or scant observation, are too often worthless, while some are written in the true spirit of quackery, to advertise the author's name and bring grist to his mill. For these reasons we ever gladly welcome such publications as the one before us.

As will be gathered from the preface, most of the articles contained in this volume made their appearance in print years ago, and are too well known and too largely quoted from to require any notice from us. In their present shape they have been revised, and many new cases added, so that, although great advances in the domains of pathology and therapeutics have been made since some of these papers saw the light, their value has not been a whit diminished, and they are yet referred to by most standard writers as authoritative.

The paper upon Compound Fractures is entirely new, being an elaborate review of the whole subject, rich in practical points such as can only result from a large public and private practice, the former, as we are told, having extended over a period of thirty years at the Pennsylvania Hospital. To those who have followed the practice of the Pennsylvania Hospital, and who, a few years back, enjoyed the advantage of listening to the clinical lectures of the author of this volume, most of the points dwelt upon will appear as twice-told tales, yet welcome, as bringing to mind forgotten details of treatment, and reviving old memories; while to those who may feel no personal interest the intrinsic value of the article is great, embodying as it does the line of treatment adopted in that time-honored hospital, which has ever been followed by a large average of success, and a thorough acquaintance with which can hardly fail to be of service to those who are called upon to treat these most interesting and serious cases. The subject is systematically arranged, and the complications are treated in detail; but our space is too limited to admit of more than a passing notice of one or two points before we commend the book to the consideration of the reader.

Immovable dressings do not receive the endorsement of Dr. Norris, at least in civil practice, nor does he think they are any better suited for the treatment of compound than of simple fractures, in which cases we have been disposed to admit their value; but in army practice they are favorably considered by the author as a choice of evils. Though our author has not met with many cases in which resection of the ends of the bones was necessary to effect reduction, yet he thinks the practice of so doing is a good one, and adduces a formidable array of standard authorities in its support. No doubt cases requiring such treatment do occur, but we believe them to be rare, and fear lest the approval of the practice may open the door to much meddlesome surgery. The vexed question so often raised as to the expediency of amputating while traumatic gangrene is still spreading, is discussed fully and fairly,—authorities who favor immediate interference being cited with even-handed liberality, though Dr. Norris has himself always waited for a line of demarcation to form, and thinks he has had no occasion to regret his course. The whole paper is replete with interest, and its style is moderate and impartial, furnishing a

marked contrast to the ex-cathedra tone and impassioned energy displayed by so many writers,—partisans of matured views and slight experience.

At the end of the volume will be found an interesting case of varicose aneurism, which, occurring as the result of the almost extinct operation of phlebotomy, has a decidedly old-time flavor about it. Ligatures were applied above and below the unopened sac, and most troublesome and repeated hemorrhage ensued, necessitating division of the sac and ligation of all the bleeding points; but even this radical measure was insufficient, and graduated pressure had to be resorted to as an adjuvant to the complete cure of the patient.

The printing and paper are excellent, and there is a general freedom from typographical errors; though on page 152 the name of the patient Summerill appears to have been substituted for that of the surgeon, Dr. Barton.

We take our leave of this book, feeling assured that those who read it will find both pleasure and profit in so doing.

GLEANINGS FROM OUR EXCHANGES.

The Statistics of Rheumatism.—Dr. Peacock, in the annual report of St. Thomas's Hospital, London, gives the following as conclusions arrived at from a careful study of eighty-seven cases of acute rheumatism:

a. The acute forms of rheumatic fever are most common in early life. The chronic forms are almost peculiar to old age.

b. The disease is more common in men than in women, in consequence of their greater exposure to cold and wet.

c. One attack of acute rheumatism predisposes to another.

d. As many as nine attacks were found to have occurred in one patient.

e. In the majority of cases the disease runs a mild course.

f. In none of the cases reported did the temperature rise above 104° Fahr.; and in only a few did it reach 103° Fahr. The highest temperature was usually found on the day after admission.

g. Very little joint-mischief is sufficient to cause a rise in the temperature.

h. The greatest risk in the course of the disease arises from cardiac complication. Over 33 per cent. of the whole number of cases showed more or less signs of it, and in most instances the heart was found affected at the period of admission.

i. Cardiac complications are most common in early life, and are more frequent in the male than in the female.

j. The cardiac mischief is not directly proportional to the severity of the fever. In a mild case the heart may become affected, while in a severe case it may remain entirely unaffected.

k. Pericarditis is most common in the slight, endocarditis in the severe attacks. The former complication is more amenable to treatment than the latter.

l. Cardiac complication, although the most formidable, is not the only one to be feared in the course of acute rheumatism. Inflammations of the lungs and pleura are not unfrequent.

m. The treatment consisted, in *acute* cases, chiefly of the bicarbonate of potash, with or without some nitrate. In the subacute, iodide of potassium and small doses of colchicum were administered. When the pain was severe, opium or Dover's powder was given at bedtime; and mercurial purges when the tongue was foul.

n. Heart-complications were combated by blisters and poultices.

o. Convalescence was aided by quinine and iron.

On the Decussation of the Nerve-Fibres in the Optic Commissure, and Hemiopia.—By means of microscopical examination of the normal organs, and by physiological experiment, carried out in the laboratories of Brücke and Meynert in Vienna, Dr. Mandelstamm finds that there is a complete decussation of the optic tracts at the chiasma, and not, as we have been taught, a merely partial one. The experiment consisted in removal of the pair of the corpora quadrigemina, and of the optic thalamus of one side, in young rabbits, and subsequent examination with the ophthalmoscope and autopsy. After seven weeks, the ophthalmoscope showed complete atrophy of all the nerve-fibres with double contours in the retina of the *opposite* eye, and perfect intactness of these in the corresponding eye. The post-mortem examination confirmed the ophthalmoscopic observation. The author ignores the existence of inter-cerebral and inter-retinal commissural fibres. According to this arrangement of the fibres, lesions affecting the chiasma in front must produce temporal hemiopia (loss of power of the inner half of each retina); lesions behind the chiasma, nasal hemiopia (loss of power in the external half of each retina); lesions in the fissure of Sylvius, lateral hemiopia; while total or partial amaurosis of one eye may be caused by disease of the opposite optic tract in any part of its length, or, of course, by disease of the optic nerve of the same side.—*Centralblatt f. d. Med. Wissensch.*, No. 22.

Artificial Respiration in the Treatment of Snake-Bite (*Indian Medical Gazette*, May 1, 1873).—Mr. Vincent Richards details some interesting experiments on the above subject, and comes to the following conclusions:

When snake-poison is injected into the areolar tissue, as is usual in the case of a bite, absorption gradually takes place. When the poison reaches the lungs, it appears to excite the pneumogastric nerve, and through the medulla and spine the phrenic and intercostal nerves, leading at first to an accelerated action of the respiratory muscles, and afterwards, as a larger quantity of poison circulates through the lungs, and the stimulus to the nerve-centres is augmented, to paralysis of them. Vomiting, which is a frequent, though not constant, symptom, probably arises from this irritation of the pneumogastric nerves. The medulla oblongata and spine are, indeed, primarily affected, and it is only as a secondary effect that the cerebral ganglia and cerebrum are involved. Presuming this to be the physiological action of the poison, it follows that a person fatally bitten dies from asphyxia produced by paralysis of the motor respiratory nerves. The indication of cure, provided the effect of the poison on the nerve-centres is not permanent, is therefore artificial respiration. Moreover, if elimination of the absorbed poison can go on, as appears to be the case, there is good reason to hope for favorable results. When, however, the amount of poison injected is overwhelming, little can be expected from the treatment. That an animal may be affected even to convulsions, and yet ultimately recover without treatment, has already been shown; and when the quantity of poison injected into the areolar tissue would, under ordinary circumstances, be just sufficient to kill, artificial respiration, if properly maintained, might frequently save life, as it does in the case of curara-poisoning.

The Action of Aconite on the Sympathetic Nerve (*The Practitioner*, July, 1873).—Dr. Frederick Bagshawe relates some cases in which the local use of

linimentum aconiti about the face and neck produced heat, swelling, and redness of the skin, injection of the conjunctiva, great dilatation of the pupil, and much-impaired sensibility. The tongue was projected somewhat to the affected side. The threefold office ascribed to the sympathetic nerve was decidedly interfered with.

1. Sensation was blunted in the parts supplied by the nerve.

2. Nervous control over the blood-vessels was withdrawn.

3. Motive power was reduced.

The small quantities of the drug capable of being absorbed through the skin seemed to attack the nerves and muscles directly in their neighborhood, and to show little disposition to enter the general current of the circulation and so paralyze the heart.

In cases of fatal aconite-poisoning the symptoms usually occur in this order:

1. Tingling and numbness of the tongue and throat, soon extending to the stomach, with local sensations of heat.

2. Failure of the circulation, evidenced by cold extremities, cold sweats, great feebleness, etc.

3. Dilatation of pupils; sight dimmed.

4. Fatal syncope.

It is to be observed that, while most of the phenomena agree well enough with the idea of sympathetic paralysis, dilatation of the pupil is exactly the reverse of the condition of iris produced in Bernard's and Brown-Séquard's experiments.

Operation for Secondary Divergent Strabismus.—Dr. Hasket Derby relates (*Boston Med. and Surg. Jour.*, July 10, 1873) a case of divergent strabismus which had existed for thirty years, and was the result of an operation for convergent strabismus. A complete cure was effected in the following manner:

The patient was etherized, and, beginning at the inner edge of the cornea, a broad flap of conjunctiva was dissected back towards the caruncle, a distance of six lines. Care was taken to thoroughly remove the subconjunctival tissue, in order that nothing might prevent the healing of the muscle at its new point of insertion. The internal rectus was found reduced in size, attached far behind and somewhat above its old position. It was divided at its insertion, dissected away from its attachments, brought forward and laid upon the cornea, spread out so as to half cover it. In this position it was secured by two sutures through the conjunctiva, above and below the centre of the cornea.

An incision was now made over the insertion of the externus, and this brought into view. A single stout thread was armed with a needle at either end. One was passed into the centre of the insertion, as near the eyeball as possible, and made to emerge through the upper edge of the muscle. The second was passed in at the same point and brought out at the lower edge. The muscle being next divided, just outside the thread, the eyeball was moved readily in any direction by means of the two threads gathered into the hand of the operator. It was rotated as far inward as possible, so that the edge of the cornea touched the caruncle, and the ends of the thread secured firmly to the opposite temple. A compressive bandage was applied.

A New Symptom of Pyelitis (*Il Morgagni*, February and March, 1873).—When any alteration is found in the urine, it is important to know whether the lesion which is its cause is seated in the bladder or in the kidney. Many diagnostic signs of pyelitis have been given, the most important being the presence in the urine of the epithelial cells which line the pelvis and the calyces of the kidneys. An excess of albumen with a normal quantity of urea and an acid reaction of the urine are, according to Oppolzer, the most reliable symptoms. M. Pascalucci, impressed with the defectiveness of our means of arriving at a diagnosis, has sought a more certain sign, and asserts that he has discovered it in the condition of the crystals of nitrate of urea. After having examined the epithelium contained in the urine, he adds some nitric acid, in order to form nitrate of urea, and then examines the precipitate microscopically. If the catarrh is limited to the bladder, the crystallization is normal; that is, the crystals assume the form of hexagonal, rhombohedric scales, arranged like tiles on a roof. In pyelitis these scales are irregular, bevelled on the angles, and often have the shape of little brushes, brooms, or feathers. This symptom, if constant, would be more important than any with which we are now familiar.

Subperiosteal Excision of Hip-Joint.—Mr. Croft (*Lancet*, June 14, 1873) read notes of a case of hip-disease in a boy seven years of age, the result of a fall. A large abscess had formed on the outer side of the thigh below the joint; it was freely incised, but, as only temporary relief was thus obtained, an excision of the joint was rendered necessary.

A slightly curved incision, three inches long, with its centre opposite the top of the great trochanter, was made down to the bone, dividing the periosteum. The soft parts were then turned aside, and the periosteum cut across at right angles to the first incision, just below the level of the small trochanter. With the bistoury, the transverse division of the periosteum was carried round all but the inner and back part of the bone. Then, with a periosteal elevator, like Dr. Sayre's, the periosteum was easily peeled back. An attempt was also made to detach the muscular insertions from the great trochanter, but this was not effected without the use of a knife. The top of the femur was sawn off with a chain saw, just below the small trochanter. This mass having been turned out by the elevator, the acetabulum was freely exposed. Five roundish sequestra, varying in size from a small to a large pea, were picked out of the floor of the space. The portion of femur removed consisted of the head, neck, and two inches of the shaft, measuring from the top of the great trochanter. The wound was partially closed by sutures. After the operation the limb was kept at rest, and extended by means of a bracketed long outside splint, or extension by weight. At the end of four weeks, passive motion was commenced. Eighteen months later, the patient was enjoying perfect health, and the femur which had been operated upon was scarcely an eighth of an inch shorter than its fellow.

The Etiology of Typhus.—Dr. Amédée (*The Practitioner*, June, 1873), in a memoir entitled "Typhus des Arabes," records some interesting facts connected with the terrible epidemic of typhus in 1868, and, among other things, gives an additional illustration of the development of the disease under conditions in which the persons apparently exciting it were not themselves in the first instance its victims.

An ancient military prison in the Rue Salluste, Algiers, had been converted into a house of refuge for the starving Arabs brought in from the environs of the city. These unfortunates were in an incredible state of wasting and anæmia, covered with rags and vermin, and gave off a peculiar overpowering odor; but they were free from typhus.

All at once, in five or six houses adjoining the prison, very grave cases of typhus appeared. Among them the following is cited:

A young baker, twenty-two years of age, convalescent from typhoid fever, and at his first going out, passed through a group of mendicant Arabs waiting for the distribution of food. He stopped a few moments to observe them. Three days after he was seized with

typhus complicated with epistaxis, confluent petechiæ, and intense delirium and other nervous disturbances, in the midst of which he succumbed after a few days' illness.

Succedanea of Quinine.—Dr. Angelo Crociani (*Imparziale de Firenze*) was led to try various succedanea of quinine on account of the high price of the drug, its adulterations, and chiefly the repugnance evinced to it by the inhabitants of Val-di-Chiona, where he practises. After various trials, the drugs which succeeded best, and which he now advocates, were iodine and sulphur. According to Dr. Crociani, the success of both these drugs is due not to any antiperiodic action, but to their antizymotic properties, thereby admitting the influence of morbid ferments and the presence of cryptogamic organisms in paludal fever. Both drugs were successful in cases where quinine and arsenic had failed. The author relates four cases of tertian ague in which sulphur succeeded, and eight cases cured by the use of iodine. The sulphur was generally administered as follows: an ounce divided into four doses, to be taken during apyretic intervals. In one case two doses were given the same evening; the following day the fit was much less intense, and as soon as it was over the patient took the two remaining doses, and entirely recovered. As to the iodine, after previous purging, ninety drops of the tincture, with three ounces and a half of strong infusion of quassia, were given, one-half the day of the fever and previous to the fit, the other half on the following morning.—*Lancet.*

Pseudo-Hypertrophic Paralysis.—Mr. Hutchinson exhibited a case of this disease at the London Hospital, and drew attention to the following features as its diagnostic points:

1. That its subjects are almost invariably young.
2. That although there is often the history of weakness of the lower extremities in infancy, and late walking and "waddling" gait after they have learned to walk, the aggressive disease never really dates from infancy.
3. That the paraplegia is slow and painless, and in its early stages not attended by any increase in the bulk of the muscles.
4. That the calves of the legs, the muscles of the lumbar spine, and the buttocks are the parts in which the tendency to overgrowth is first shown.
5. That simultaneously with the overgrowth of the parts mentioned, there is usually progressive weakening of the muscles higher and higher up.
6. That the sphincters do not suffer, that constipation does not occur, and that the nerve-supply to the iris is not altered.
7. That there are no contractions of the affected muscles.—*Lancet*, July 12, 1873.

Treatment of Gastralgia.—For the treatment of gastralgia Dr. Joulin strongly advocates (*France Médicale*, June 7) a combination of ice and external revulsants. The chief points of the plan may be summed up thus:—1. A poultice of ice for ten minutes, morning and evening, to the pit of the stomach. 2. A mustard plaster to the same spot immediately on removing the ice-poultice, to be kept on as long as possible. 3. Pounded ice, to be taken morning and evening, a tablespoonful every five minutes for one hour. 4. A mustard bath with two pounds of mustard three times a week. The ice of the poultice is to be chopped up in small bits and enclosed in an india-rubber bag. The ice taken internally must be pounded with sugar, or it may be prepared to the taste of the patient. It must be swallowed down suddenly, and not kept in the mouth, as it would lose its coldness. If a tablespoonful is too much at a time, several teaspoonfuls may be taken instead. As to the general mustard bath, Dr. Joulin recommends it as far superior to the ordinary warm bath, which weakens, and considers it to be a powerful tonic which affords the best results in nervous women. The duration of the treatment varies according to the intensity of the symptoms, from simple dyspepsia to general neurosis, but the whole treatment must be employed in every case.

Herpes consecutive on Traumatism.—Professor Verneuil distinguishes three kinds of the above:—1. Peripheric herpes, supervening towards the extremity of the diseased nerve (a nerve being wounded in its continuity, herpes manifests itself between the lesion and the terminal development); (2) herpes of neighborhood (*herpès de voisinage*), observed on the strips of surface innervated by the collateral branches of the injured nerve, either through ascension and propagation of the neuritis to those branches, or through reflex action, which it is difficult to admit; (3) distant herpes (*herpès à distance*), situate in a region far from the seat of injury, and which has therewith only an indirect nervous connection, existing exclusively through the ganglia or even the cerebro-spinal centre. Traumatic herpes, according to Dr. Verneuil, is dependent upon the constitutional condition. He also thinks that what is called diphtheria of wounds is perhaps only an herpetic complication at times. On the other hand, he thinks that a reservation must be made touching phlyctenoid erysipelas, as the phlyctens which serve to characterize this sort of erysipelas may often be simply herpetic vesicles circumscribed by cutaneous inflammation.—*Lancet.*

MISCELLANY.

During a botanical exploration of the region around the river Coanza, in Lower Guinea, Dr. Welwitsch's party found their supply of provisions exhausted. The men accordingly went in search of food, with senses quickened by hunger. They were so fortunate as to discover an enormous mushroom, as large as an umbrella, which made soup enough to satisfy the hunger of twenty men. This specimen was the first of the species seen by Welwitsch, but subsequently he often met with it, and learned that these great mushrooms are brought to market at Pungo Adongo by the natives, and there sold at from one to three pence each, according to size.—*Popular Science Monthly.*

The staff of the Harrisburg Hospital, seeing in the daily papers the action of the Board of Managers relating to homœopathy, sent a committee to ascertain whether that action would be adhered to; and, after being assured emphatically that the resolution would be enforced, they handed in the following:—

"*To the Board of Managers of the Harrisburg Hospital:*—Gentlemen,—The undersigned respectfully represent that when we accepted the respective positions to which you elected us upon the staff of the hospital, we did so under the impression that the medical and surgical treatment of its patients would be intrusted entirely to our care; as they are to the staff of every regular hospital.

"You have seen fit, subsequent to our acceptance, to pass the following preamble and resolution:

"'*Whereas*, It has been stated that if homœopathic

medicines be procured, attendance will be furnished gratuitously by a homœopathic physician: therefore,

"'*Resolved*, That a case of homœopathic medicines be procured, at a cost not exceeding $100, so that if any patients wish to be treated under that system it may be done by a physician of that school.'

"Whilst we should cheerfully and gratuitously have served the interests of the institution to our best ability, as its sole staff, we cannot consent to act in a hospital wherein it is proposed to sanction practice so utterly at variance with that in which we have been educated.

"We, therefore, hereby respectfully tender our resignation.

"H. O. Whitman, M.D., Consulting Physician.

"George Dock, M.D., Consulting Surgeon.

"G. S. Hursh, M.D., John W. Hay, M.D., Visiting Physicians.

"H. L. Orth, M.D., A. C. Renninger, M.D., Visiting Surgeons.

"John C. Hutton, M.D., Hugh Hamilton, Dispensary Physicians.

"HARRISBURG, PA., August 6, 1873,—3 P.M."

[The committee who waited upon the attending manager volunteered, by instruction of the staff, to continue their services until the manager could make suitable arrangements for the care of the patients.]

"*To Drs. Whitman, Dock, Hay, Hursh, Orth, Renninger, Hamilton, Hutton:*—GENTLEMEN,—The Board of Managers of the Harrisburg Hospital, at a meeting this day, accepted your resignation as the medical staff of said hospital.

"With great respect,

"Your servant,

"A. BOYD HAMILTON,

"*Secretary.*

"HARRISBURG, PA., August 7, 1873."

"At a special meeting of the Dauphin County Medical Society, held this evening, the following action was taken:

"*Whereas*, The Board of Managers of the Harrisburg Hospital, having elected a competent medical staff of regular physicians, did, by the following resolution, passed subsequently to the said election,—viz.:

"'*Whereas*, It has been stated that if homœopathic medicines be procured, attendance will be furnished gratuitously by a homœopathic physician: therefore,

"'*Resolvèd*, That a case of homœopathic medicines be procured, at a cost not exceeding $100, so that if any patients wish to be treated under that system it may be done by a physician of that school,'—attempt to introduce into the hospital a pretended system of medicine: therefore,

"*Resolved*, That we cordially approve of and endorse the action of Drs. Curwin and Reily in resigning their positions upon the Board of Managers of said hospital.

"*Resolved*, That we also most cordially approve and endorse the manly and high-toned professional action of the medical staff in promptly resigning their positions in said hospital.

"*Resolved*, That we individually and as a society hereby pledge ourselves not to accept any position in said hospital unless each and every member of the late staff of the hospital be re-elected by the managers of said hospital, and all other practice but that of the regular school of medicine be ignored.

"R. H. SEILER, M.D.,

"*President.*

"HARRISBURG, PA., August 7, 1873."

GASTRO-INTESTINAL INSUFFICIENCY.—The editor of the *Nashville Medical Journal* thus discourses in regard to those who affirm that the cholera at Nashville was merely a local outbreak of gastro-intestinal disease from filth: "May, 1873, sent to the 'bivouac of the dead' seventeen remains of mortals, and June of the same year sent more than one thousand! 'Oh, the filth of Nashville!' cry out ring-makers, job-hunters, croakers, and repeaters. Tell us, O ye faithful, if there was not as much filth in Nashville on the 9th day of July, with two burials, as on the 20th of June, when a hundred of our people were buried out of our sight. How is it that filth is so potent upon the one day and so impotent on the other? 'The scavengers,' you say, 'and a hundred carts, *ad interim*.' Bah! A thousand ants upon the Augean stable! Are we to repeat the stormy medical annals of 1793, and make a cart-load of rotten coffee on the quay the cause of grass growing on the streets of Philadelphia, and the seaming and ploughing of her cemetery by the remorseless application and punctuality of her undertakers? Did Nashville do this *per se?* Can she do it? If so, then farewell Nashville—pleasant Nashville—polite, elegant, cultivated Nashville."

DR. LYON PLAYFAIR has no very high opinion of the value of English university education. He said recently in Parliament that "a Scotch university teaches a man how to make a thousand a year, an English university how to spend it."—*Popular Science Monthly.*

THE FIRST OPERATION OF LITHOTRIPSY IN AMERICA.—Dr. Alban Goldsmith, the first assistant to Dr. McDowell in many of his ovariotomies, made the first operation of lithotripsy ever performed in Kentucky or in the United States. It occurred in 1829.

WE understand that Mr. Jonathan Hutchinson has sent in his resignation as surgeon of the London Hospital, a post he has held for the last ten years.

IN consequence of the appearance of cholera at Venice, passengers for India or Egypt are advised to avoid that city.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM AUGUST 12, 1873, TO AUGUST 18, 1873, INCLUSIVE.

TILTON, H. R., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, to take effect September 1, 1873. S. O. 151, Department of the East, August 11, 1873.

LAUDERDALE, J. V., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Wadsworth, N. Y. H., during absence of Assistant-Surgeon Tilton. S. O. 151, c. s., Department of the East.

SATURDAY, AUGUST 30, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF TRAUMATIC MÉNIÈRE'S DISEASE.

Delivered at the University of Pennsylvania,

BY DR. H. C. WOOD, JR.

GENTLEMEN,—The man before us to-day presents himself partly for treatment, but more especially for an opinion as to whether there is or is not a pistol-ball within his cranium. The history which he gives of himself is as follows. Three months ago, whilst sitting talking with a friend, he was wounded by a pistol accidentally discharged in the hands of the latter. So near was he to the muzzle of the weapon that, as you can yet see, his face was covered with the grains of powder, many of them being driven into the skin. The direction of the ball was believed to be horizontal or a little downwards, and you can readily perceive, just above the left corner of the mouth, the scar of its entrance. He did not become at once unconscious, but for the twelve hours after the accident was, so far as I can judge from his description, in a semi-unconscious condition. The symptoms from the local injury were severe; inability to talk or to eat anything except liquids, with great swelling and soreness about the mouth, persisted for about two weeks, and with such intensity as to overshadow all other symptoms. It is important to mention that at the time of injury there was slight but persistent hemorrhage from the right ear, and that shortly afterwards he noticed that he was deaf on the same side.

Two or three weeks after the reception of his injury, he was sufficiently recovered to sit up in bed and to attempt to shave himself. It was then that he first noticed an inability to make the finer movements with the right arm, and also a decided loss of power in executing the coarser ones. He was entirely unable to shave himself, and has been so ever since. On attempting to walk, he found that his right leg was very decidedly weaker than its fellow.

The present condition of the man may be summed up as follows: Complete deafness of the right side, as shown by holding a watch against the ear; speech somewhat thick and staggering; pupils alike on both sides, and normal; optic disk normal; no headache; pains of the right arm and leg decided; the muscles flabby, but responding sluggishly to electricity.

Evidently the first point in the case to be determined is as to the position of the ball, whether it is or is not inside the skull.

As incomplete hemiplegia exists, you might at first glance be tempted to believe that the brain-substance had been wounded. Notice, however, that the paralysis is far from complete, and especially that it is upon the side of the injury. From the direction of the shot, it would seem impossible that the ball could have crossed to the opposite side before entering the brain; and the occurrence of the bleeding from the right ear at the time of injury demonstrates that this did not happen. As decussation of the motor fibres of the brain takes place first in the medulla oblongata, it is evident that no pistol-ball could produce a brain-wound which should in its turn induce a paralysis of the same side of the body without causing more serious symptoms than have existed in the present case. A gunshot wound of the medulla is necessarily fatal. It seems to me to follow from these considerations that the loss of power in the arm and leg of this man is not due to an injury of the brain-substance. The absence of headache, with the perfectly normal condition of the optic disk, appears to me inconsistent with the idea of meningitis; and I am forced to conclude that the paralysis is not of central origin, and that the ball did not find its way into the cranial cavity. Further, it would appear most probable that the missile is imbedded in or lies near to the petrous portion of the temporal bone, since the almost complete deafness and the persistent bleeding from the ear at the time of injury showed that the bone alluded to was fractured.

No doubt many of you are now inquiring within yourselves how the loss of power of the muscles of this man is to be accounted for if the nerve-centres were not affected, and what fracture of the petrous process has to do with the paresis. My answer to the first inquiry is, Wait a moment; to the second, Much. As long ago as 1842, the great physiologist Flourens discovered that lesions of the semicircular canals in the lower animals are followed by disturbances of equilibrium and of motion, and that if the horizontal canals be wounded rotary movements *towards the injured side* occur when the animal attempts to walk.

One of the chief complaints of our patient is, that he staggers; that at times in walking the streets his gait has been so uncertain that his acquaintances have thought that he was drunk. This staggering, he states, is much worse at night than in the daytime,—in the dark than in the light. You see now when he walks with his eyes open he is quite steady; but watch him as he attempts to walk around the amphitheatre with his eyes bandaged, and see how he staggers. Notice, if you please, that the staggering is towards the affected side. The patient asserts that it is always so. As injury to the internal ear will in animals produce very marked disturbances of motility, similar in character to those which are present in the case before you, and as in the patient the history shows that the inner ear was injured, it appears to be a fair logical inference that his symptoms are due to the aural injury. This diagnosis, however, does not rest simply upon experimental physiology for its basis, but has also clinical support.

In 1861, Dr. Paul Ménière described an affection which has since been noted by various observers, and is known by the name of its discoverer. In this disease the patient suddenly falls, unconscious, as if in apoplexy, and, on recovering consciousness a

few moments afterwards, discovers that he is totally deaf in one ear; or else this sudden deafness is preceded simply by an intense vertigo, and not by a complete apoplectiform attack. With this deafness there is almost always tinnitus aurium, or ringing in the ears, which is more or less permanent, and is accompanied by disturbances of equilibrium and staggering, or rotatory movements, towards the affected side.

For an elaborate discussion of the subject, I must refer you to Dr. H. Knapp's paper in the second volume of the *Archives of Ophthalmology and Otology*. It is enough for our purpose to know that the symptoms of this affection have their origin in an apoplexy of the internal ear, in all probability of the semicircular canals. In the same volume of the *Archives*, Dr. G. Brunner, of Zurich, details a case which demonstrates very strongly the relation between apoplectiform symptoms and disturbances of the pressure upon the nervous expansion of the inner ear. Into the inner ear of a lad fourteen years old he suddenly and violently forced air, with the result of producing intense vertigo and temporary hemiplegia, which Dr. Brunner believes to have been upon the same side as the ear acted upon, although, writing from memory, he is not certain as to this.

With a knowledge of these facts, I think you all will agree with me in diagnosing that all the cerebral symptoms in the case before us had their origin in a fracture running through the inner ear, and in prognosing that, as the local disturbances caused by this subside, the power will return to the arm and leg. With the idea of hastening the removal of any exudation which may exist, I will give the man small doses of Donovan's solution, and will see that the health of the affected muscles is restored by faradization, kneading, and the other usual local measures.

[Under this treatment the man recovered the full use of the affected limbs, and ceased almost entirely to stagger in about six weeks. The hearing improved slightly.]

ORIGINAL COMMUNICATIONS.

A CASE OF UNSUSPECTED PUNCTURED WOUND OF THE BRAIN-SUBSTANCE WITH SUPPURATIVE ENCEPHALITIS.

BY W. H. PARISH, M.D.,

Late Resident Physician to the Philadelphia Hospital.

THOMAS B., æt. 64 years, was discharged from the drunkards' ward of the Philadelphia Hospital on September 24, 1871, and on the 2d of the following month was again received into that ward; it now being his twelfth admission to the house. Shortly after his admission he was seen by one of the physicians, who, not considering him sufficiently under alcoholic influence to render it necessary that he should be kept in that ward, and observing a small wound of the temple, had him transferred to the surgical ward. There, on the 3d he stated to the interne that there was nothing the matter with him, and that he wanted to be sent to the out-wards. The interne, finding him walking around, perfectly rational, free from any suffering, with only an apparently very slight integumental wound, and asking to be transferred, had him sent from the crowded surgical wards to the out-wards. There the officer in charge placed him among those capable of doing light work, so entirely well did he appear.

The man made no complaint until the afternoon of the 5th, when he took to his bed, saying that his head ached and that it was hard for him to breathe.

About 10 o'clock of that night the physician of that apartment was sent for. The patient was then in a very delirious state, and gave no answer to any question. Early on the following morning he was again taken to the drunkards' ward.

On the 6th, about 9 A.M., he was seen by Dr. Eshelman, and, at the latter's request, by myself, for the first time.

The patient was then motionless and speechless. The respirations were slow and stertorous, with puffing of the cheeks on expiration. The pupils were fixed, the left contracted, the right about normal in size. There were some oscillations of the eyeballs. Touching the conjunctiva produced no muscular action of the lids. The pulse at the wrist was slow and full. The bladder, being distended, was emptied by catheterization. We then observed a small wound of the right temple, it being partly concealed by hair matted with pus; but, owing to the obviously moribund condition of the man, it was not further examined. An enema unloaded the rectum. Some milk-punch was given, deglutition being accomplished, but with difficulty.

The state of complete coma continued, without convulsions, until 11 P.M., when death occurred. At no time prior to the coma was there complete paralysis of any muscle.

Fifteen hours after death, in the absence of Dr. Eshelman, I made the autopsy. There were no bruises or other marks of injury on the person, excepting the small wound of the right temple. This was about half an inch in length and situated about one inch in front of the tragus. The cranial cavity was first examined. Passing through the squamous portion of the right temporal bone, immediately above the zygomatic arch, was found the small blade of a pocket-knife, it entering the middle cerebral lobe and being directed transversely and somewhat posteriorly. The blade measured about two inches, and its shoulder was in contact with the external plate of the bone. The blade had not been broken, but wrenched from the rivet. The portion external to the cranium was completely concealed by the integument. There were no evidences of hemorrhage within the cranial cavity. The base of the brain was covered with a thick purulent fluid. The meninges of the vertex presented no signs of inflammation.

On the 9th the body was seen by the coroner's physician. I then continued the examination of the brain. The knife had entered the middle lobe from the side, piercing apparently through to the middle cornu of the lateral ventricle. Around the blade the brain-tissue had broken down, leaving the cavity of an abscess. The tissue around was softened, and presented the diffused pinkish appearance of encephalitis with œdema. The microscope exhibited numerous granular fat-cells—the "globules of Gluge"—throughout the inflamed cerebral substance, this being apparently quite limited to the middle lobe. The two lateral, third, and fourth ventricles contained a few ounces of a turbid purulent fluid. At no point was there to be found lymph undergoing organization.

A triangular portion of the calvaria, including the knife-blade, firmly impacted, was sawn out. The bones were of about the usual thickness. There was no depression of the internal plate, and no lines of fracture radiating from the point of puncture.

Remarks.—On the day of the man's admission to the hospital it was noticed that the wound of the temple was in a state of suppuration, and consequently must have been produced several days previously. Most probably, then, the blade had remained imbedded in the brain-substance for six or more days prior to his death, or even to the first manifestations of cerebral derangement. The wound having been inflicted while the man was in a state of debauch, no evidence as to the mode of its production could be obtained. It is common to meet with slight contusions or other wounds on those subject to debauchery, which under mere hygienic hospital regulations get well of themselves. In this instance, prior to the evening preceding his death, there were no symptoms to awaken even a suspicion that this would prove an exceptional case.

The patient continued to walk around, rational, yet not aware that there was anything wrong with his head. When the suppurative encephalitis became so extensive as to involve the basilar meninges, producing irritation and, from the accompanying exudation, compression of the nerve-roots, pain, severe and intense in its character, became the earliest and one of the most important symptoms. As the roots of the pneumogastrics became implicated, difficulty of respiration presented itself. Soon the manifestations of active psychical derangement evinced that the entire encephalic mass was sympathizing with the intensity of the inflammatory action, though this was confined to a limited portion of this nervous centre. As the exudative material now rapidly accumulated, and the congestion with œdema of other portions of the brain became more marked, complete coma from compression supervened.

The symptoms on the 6th were very similar to those of apoplexy, but the unsymmetrical condition of the pupils pointed rather to a laceration of the brain-tissue with compression, than to simple compression alone. In laceration without compression the pupils are usually contracted; as compression complicates the case, we generally find one contracted, the other dilated. Suppurative encephalitis is usually due to traumatism. It also arises from disease of a cranial bone, or may have its origin in a necrosed spot, or may show itself in pyæmia, typhus, or other low diseases, or it may be idiopathic. It is much more common in adults than in children, being the reverse of meningitis in this respect. It never involves all the cerebral mass, the inflammation being confined to one or more localized spots, unless there is such an affection as *cerebria*,—the existence of which does not seem to be satisfactorily established.

Among the symptoms frequently present, though apparently not in this case, are twitchings, rigidity or paralysis of isolated muscles, and general convulsions.

Treatment may at times prevent suppuration, but to effect this it must be strictly antiphlogistic. After the formation of pus, or after the actual softening of a portion of the brain-tissue, treatment is of almost no avail. It is said that in some few exceptional cases an exudative material has encapsulated the softened mass, and that the latter has been in part gotten rid of by absorption, in part changed by calcification.

This case is one of considerable interest, but is by no means unique. Numerous cases are cited in the various surgical works. Sir Astley Cooper instances a case of a girl, through the orbital plate of whose frontal bone the blade of a pair of scissors was accidentally thrust, it entering the brain-substance. The blade was immediately withdrawn, and the girl continued to walk about for ten days, when encephalitis was established, and she quickly died.

Erichsen gives two cases of abscess of the brain following laceration of the pericranium. In the one case there appeared on the tenth day pain in the head, quick pulse, and a hot skin; and on the thirty-ninth day the man died comatose. In the other case there was coma on the ninety-ninth day, and on the third subsequent day death. In each case autopsy showed central abscess without injury of the bones.

From the same authority we also learn that Dr. Cunningham relates the case of a boy who lived twenty-four days with a pistol-breech lying on his tentorium and resting against the occiput; and that Dr. O'Callaghan relates that an officer lived seven years with the butt of a fowling-piece imbedded in his forehead, and in contact with the right hemisphere with the exception of an intervening adventitious membrane.

The most remarkable case of all, however, is the one reported by Prof. Bigelow in 1850. In that one an iron bar, three and a half feet in length by one inch and a quarter in diameter, passed through the anterior portion of the cranial cavity. In sixteen months there was complete recovery, save the loss of vision in the eye of the injured side.

There are at least three instances in which the surgeon has boldly incised the healthy brain-substance to reach a diagnosed cerebral abscess, and in every instance with the success of evacuating the contents and of improving the condition of the patient. These operators were Dupuytren, Delmot, and Prof. Pancoast.

The question naturally presents itself, Would the termination of the case that we have reported have been different had the nature of the injury been ascertained soon after its infliction and the foreign body been immediately removed?

A wound of the cerebral substance occurring in the aged and in those subject to a state of confirmed alcoholism, the chances against a favorable termination are much enhanced; and most probably the injury was an inevitably fatal one, even had circumstances permitted the most prompt and judicious treatment.

The subsequent coroner's investigation threw no light upon the production of this wound. The position of the injury, and the force which must have been used to accomplish it, would seem to indicate that its infliction was scarcely possible by the hands of the man himself, and it was, therefore, almost certainly done by some one else in a drunken brawl.

EYES OF DIFFERENT COLORS IN THE SAME INDIVIDUAL.

BY JOHN STOCKTON-HOUGH, M.D.

THE writer has recently seen quite a curious and perhaps very unusual phenomenon,—viz., eyes of different colors in the same animal. Two entirely white male cats, brothers, of the same pregnancy, were alike in every particular save one, and that was in the color of the eyes (irides). One cat had both eyes of a corn color; the other had the left eye corn-colored, and the right a very light blue in color. The effect of this difference in color was so striking as to attract my attention to them when I was passing the open doorway in which they were standing. I did not learn any particulars concerning the color of the father's eyes, but the mother had both eyes of the same color.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS.

RE-FRACTURE OF DEFORMED CALLUS IN A CASE OF BADLY-UNITED FRACTURE OF THE FEMUR.

DANIEL G., a sailor, aged 17 years, while on a voyage from Liverpool, fell from the mizzen-topsail yard, a distance of seventy feet, striking on the railing over the cabin. He sustained a fracture of the right femur, and a double fracture of both bones of the right forearm.

The mate of the vessel, acting as surgeon for the occasion, rudely bound splints to the broken limbs, but used no means for keeping up extension on the thigh. While at sea, the boy became delirious, and tore the splints and bandages from his leg, so that the fragments were not kept in apposition, and great deformity resulted. The upper fragment of the femur was tilted upwards and rotated outwards by the action of the psoas and iliac muscles; and union consequently took place with the bones in an angular position.

On his admission to the hospital, which was just five weeks after the injury, there was great shortening, angular deformity, and a large amount of irregular callus. The right thigh was found, upon measurement, to be three and a half inches shorter than the left.

Hoping that complete consolidation of the callus had not taken place, the resident surgeon attempted to effect extension by the traction of a heavy weight continued for several days, but without success. As the difference in the length of the two limbs was so much that great lameness must necessarily ensue, it was determined to re-fracture the deformed callus, and to endeavor to effect a cure without much deformity.

After more than six weeks from the receipt of the original injury, a splint was bound along the leg and thigh up to the deformed union, to make the knee rigid, and to give a powerful leverage. The knee of the operator was placed as a fulcrum on the most salient point of the deformity, and the callus was broken up by leverage of the limb and splint. Extension was then made by manual force, and was afterwards continued by means of a weight of twelve pounds applied by adhesive straps, as in ordinary treatment of fracture of the thigh. The amount of shortening was reduced to three-quarters of an inch; and this will probably decrease under the continued weight extension. The patient is now doing well, and there is every prospect of his having a useful limb.

The case illustrates how firmly a mal-apposition may be consolidated in a period of six weeks, and how by re-fracture and extension the most of the shortening and deformity may be at once overcome.

INJURY OF SPINE, PROBABLY FRACTURE—PARALYSIS—DEATH OF THE PATIENT.

A laborer, aged 40, was digging a well, when the rope by which the earth was raised to the surface parted, and the loaded bucket, weighing one hundred and seventy-five pounds, fell upon him from a height of thirty-five feet. The tremendous blow received on the head forced the spinal column into extreme anterior flexion; and at the limit of flexibility the spine received a severe strain, or was fractured.

The portions of the spinal column which most generally receive the greatest injury in such form of indirect violence are the points where the greatest amount of flexibility meets with resistance. The points where the flexibility meets inflexibility, and where there is the greatest latitude of motion, are at the cervico-dorsal and dorsi-lumbar articulations; and experience shows that these localities almost universally suffer the most. The position of the injury in this case is at or near the dorsi-lumbar junction, where it is almost always found, and, as a consequence, the man had complete paralysis of motion and sensation of the body and lower extremities below the umbilicus, and was unable to void the contents of the rectum and bladder. He breathed by the diaphragm and intercostals, without any aid from the abdominal muscles.

The gravity of spinal injury is in proportion to its position high up in the vertebral column. Should inflammation extend up the cord, the intercostal muscles would be paralyzed next, because the phrenic nerve, which goes to the diaphragm, comes off from the third, fourth, and fifth cervical, while the intercostal nerves are derived from the dorsal branches of the cord. The patient, however, would not necessarily die, when even the intercostal and abdominal muscles were paralyzed, for there have been cases in the hospital where men have lived a week breathing by the diaphragm alone, or with possibly the aid of the serratus magnus anticus; though it would seem that respiration cannot be kept up very long solely by the action of these muscles.

The abdomen was distended and tympanitic, on account of the want of tonicity and pressure of the abdominal muscles, and probably also because the paralyzed state of the lower bowel prevented the expulsion of flatus. Dr. Levis stated that, in severe spinal injury, for the first few days the bowels are obstinately constipated, and there is retention of urine in the bladder necessitating the introduction of the catheter, but that the sphincters soon become so entirely relaxed that urine and fæces are voided without the control of the patient.

The diagnosis of fracture in this case was not certain, as there was no marked evidence of displacement, and shock or violent sprain by anteflexion would be sufficient to produce the paralytic symptoms. It was found that there was some sensation of the integument a short distance above the umbilicus; but there may be sensitiveness of the skin when the underlying muscles are paralyzed. Dr. Levis said he had seen an instance of sensitiveness of the skin on the front of the chest in a case of fracture of the spine high in the dorsal region, which is readily explained, as branches of the superficial *cervical* plexus descend over the front of the thorax.

The only treatment pursued in the case was to let the patient lie in the supine position on the bed, which acts as a splint, supporting the injured parts and giving the patient the most comfort. In order to prevent, as far as possible, the occurrence of bed-sores, a water-bed

was employed; but this only delays their development in a measure, for since the innervation of the parts is interfered with by the injury of the spinal cord, the least continued pressure on the heels and sacrum forces the blood from the capillaries, and sloughing invariably follows.

The region of insensibility, as tested by a sharp point touching the skin, was very evidently increasing, and one week after the receipt of the injury the patient died, probably from inflammation and effusion up the course of the cord, and interference with the innervation of the respiratory muscles, which is probably the most frequent cause of death in spinal injury.

THE RADICAL TREATMENT OF HYDROCELE BY INJECTION OF CARBOLIC ACID.

A man came to the hospital suffering from a hydrocele of the vaginal tunic of the testicle on the right side, which he stated first began to trouble him a year previous. Six weeks before his admission it had been tapped, and more than a pint of fluid was drawn off, but it rapidly re-developed, and he accordingly presented himself for radical treatment.

As the ordinary mode of treating hydrocele by injecting tincture of iodine into the sac is sometimes unsuccessful, and at other times is followed by an excessive degree of inflammation, and even by suppuration, it was determined to employ carbolic acid as an irritant, which would, it was believed, excite sufficient inflammatory action, and yet, as it checks the formation of pus when externally applied, would have a tendency to limit the inflammation in the sac within the degree of suppuration.

After the serous fluid, which amounted to a pint, had been drawn off by the trocar, the operator injected into the vaginal tunic two fluidrachms of a solution of carbolic acid in glycerin, in the proportion of one part by weight of crystallized acid to two of the menstruum. He then, by manipulation, brought the fluid in contact with every portion of the serous surface, in order that the approximated sides of the sac might be rendered adherent by lymph thrown out upon the supervention of plastic inflammation. The patient did not experience any pain whatever from the introduction of the fluid, such as is the case when tincture of iodine is injected, and which is severe and extends along the course of the genito-crural nerve. It was thought that this painlessness of the procedure might be due to the fact that carbolic acid is capable of inducing local anæsthesia.

At the end of twenty-four hours the tumor was quite large, but had rather a doughy feel, and there seemed to be more inflammation present than generally exists one day after the usual iodine injection has been used; but the swelling was neither painful to the patient nor very sensitive to pressure.

The remarkable feature of the case is the almost entire absence of pain in this method of treating hydrocele.

Carbolic acid seems theoretically to meet all the requirements of the radical cure of hydrocele; but it will require continued experience to determine the practical value of this new method of treatment.

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,
Of Philadelphia.
Reported by J. Ewing Mears, M.D., of Philadelphia.

CASE 244.—*Multilocular ovarian tumor accompanied by ascites—Paracentesis abdominis performed forty-seven times—Three thousand two hundred and eighty-eight pints of fluid removed during a period of three years—Incision five inches in length—No adhesions—Recovery.*

October 12, 1871, Dr. Atlee visited Miss M. A. A., at the request of Dr. B. F. Hamilton, of Emlenton, Venango County, Pennsylvania. The patient was forty-four years old; menstruation commenced at the age of thirteen, had always been regular, and had never been painful until she became dropsical.

Dr. Hamilton gives the following history of the case: He saw Miss A. October 15, 1868, in consultation with Dr. Wallace, of Brady's Bend, at which time he found the abdomen enormously enlarged, and learned from the patient that the enlargement was first noticed four years before this visit. She also stated that about one year ago the wall of the abdomen gave way at the umbilicus, permitting about one gallon of fluid to escape; through this opening the fluid discharged for several days. The general health of the patient was much impaired; there was great emaciation; the complexion was sallow; orthopnœa existed; the bowels were constipated, the urine scanty, and digestion was bad. On consultation, it was decided to perform paracentesis abdominis, which was done by Dr. Wallace, removing eleven and one-half gallons of a dark reddish-brown fluid. The operation was followed by symptoms of great prostration, which were relieved by the administration of stimulants.

She was placed upon full doses of quinine and tincture of the chloride of iron three times daily, under which treatment her general health improved, although the fluid began to reaccumulate.

On the 30th of November Dr. Hamilton tapped the patient again, removing ten and one-half gallons of fluid, of the same consistence, but much lighter in color. After the removal of the fluid he detected a solid tumor in the left lumbar region, apparently about the size of an ordinary placenta. As before, her health improved after the tapping.

The fluid reaccumulating, the patient was repeatedly tapped, and up to November 28, 1869, the tumor did not appear to have increased in size. On that day she was seized with a chill, followed by fever, and great tenderness over the entire abdomen, with acute pain at the seat of the tumor. A diagnosis of inflammation of the tumor with peritonitis was made. In eight days the symptoms of inflammation subsided, and the patient convalesced slowly.

January 5, 1870, tapping was performed, removing six gallons of fluid. The tumor was found to be growing rapidly. After this the patient was tapped very frequently, and the tumor continued to increase in size.

Dr. Hamilton states the total number of tappings to have been forty-seven, removing in all four hundred and eleven gallons of fluid.

Ovariotomy was performed, and the patient recovered.

Dr. Hamilton stated to Dr. Atlee that he believed it to be a case of ovarian tumor accompanied by ascites, which statement was confirmed by the operation.

TRANSLATIONS.

SYPHILITIC INFECTION WITHOUT COITUS.

From the German of Professor Lewin.

BY DR. WM. ASHBRIDGE.

(Concluded from page 731.)

6. THAT the more advanced and intense manifestations of syphilis can show themselves in cases in which no mercury has been administered. The physicians who are opposed to the use of this drug in syphilis

are, as is well known, divided into two classes, one of which supports the view that mercury is in a greater or less degree the cause of all tertiary symptoms, while the other asserts that only particular forms of these affections are due to this influence, as in the statement of Barensprung that "the tertiary forms occur especially in those to whom quicksilver has been early and carelessly given," and "it is too much to assert that they [*i.e.*, tertiary symptoms] are entirely due to mercury, for they never occur as the consequence of the treatment alone, but, as they always bear the stamp of the original disease, they must be regarded as the fruits of syphilis occurring in a constitution already injured by mercury."

Although from many sides this accusation against this mode of treatment has been disproved, and especially by the proof by Virchow that the original syphilitic affection, "the hard chancre and condylomata, have the same history of development as the deposits which are looked upon as the distinctive mark of tertiary changes," still, cases like this of children with tertiary affections born from mothers by whom mercury has never been used have a more decided influence in argument.

7. The case of the child of the mother infected by the sore on her lip is an important one in yet another respect. To which parent did it owe its disease? The father at the mother's infection had a specific ulcer upon the lips, which most probably was not an initial lesion, but an erosion or induration of later date, possessing infecting power. Ulcers of this character occur in somewhat advanced syphilis, at least several months after infection. For this reason, there is nothing opposed to the supposition that in this case the father endowed the embryo with syphilis at the time the mother was impregnated, thus furnishing an instance of the infection of the embryo through the seminal fluid of the man, the mother not being infected through this channel, an occurrence probably somewhat rare, asserted as possible by some eminent authorities, but denied by others.

8. That the appearances due to hereditary syphilis in full bloom at the time of birth can gradually enter into a state of latency. In this child, at the time of admission into the hospital, four weeks previous to the date of the lecture, in addition to a well-marked papular eruption on the skin there was also a plentiful crop of pustules of various sizes up to that of a pea; at this time the first-named eruption had faded to a trace, the pustules had dried, and the crusts had fallen. The subcutaneum and the affection of the testicle were undergoing like changes. To prove that this period of latency can extend over a period of years, and thus allow the possibility of a syphilis congen. tarda, the second group of patients—composed of a mother, two daughters, and a grandchild—was presented. The mother, a woman of forty-nine years, of a healthy family, and herself of a good constitution, had been twice married, and was the mother of two children. Up to her twenty-fifth year she had always been healthy; at that time she bore her first, which she suckled herself. Owing to the abundance of her milk she took a second child to nurse, which, as was demonstrated later, was the offspring of a syphilitic mother, was affected with congenital syphilis, and finally infected the breast of its foster-mother, upon which a sore made its appearance. The woman, not knowing the character of the sore, continued suckling her own child, so that it was infected per os. The disease was at once recognized by the physician who was called in, and a careful mercurial treatment was carried out in all three cases. The strange child, the source of the mischief, after some months died; but the infected mother, with her child, after having suffered for some time from severe throat-affections, apparently recovered. It soon became evident that the husband and father was also infected; eruptions quickly made their appearance, going on to the more severe pustular forms, accompanied by nodes upon the forehead. Gradually symptoms of brain-disease came on, which at last rose to such severity that an apoplectic attack resulted; in a soporose state the man was brought to the hospital, where he soon died. At the autopsy (made twenty years before the date of this lecture) evidences of softening of the brain, and clots, both old and new, were found, and in the absence of any other cause for the disease the changes found were adjudged to be due to syphilis. Some time after the death of her first husband the woman married a second time; the second husband being a man who up to that time had been perfectly healthy, but who, shortly after marriage, suffered much from troubles in his throat, and also from rheumatic pains, but was still living and in good health. In the woman the syphilis reappeared several times, leaving marks of its ravages in the larynx and pharynx, as could plainly be seen by the use of the laryngoscope. She soon became pregnant, and by the eighth month was delivered of a child which died from constitutional syphilis at the age of five and a half months. A second child was born, a girl, who was still living, aged thirteen years; she was healthy up to her sixth year, when a pustular eruption appeared, and for the treatment of this she came to Professor Lewin. A temporary cure was effected by a course of mercurial treatment, but after two years an ulcerated form appeared, which continued to reappear at intervals, but gradually assuming a milder type. At this time the girl was to all appearance healthy, and nothing about her attracted remark, except a universal adenitis somewhat pronounced. The history of the elder sister, who was infected from the nipple of her mother, is also of importance. In the throats of both mother and daughter were marks of their former sufferings, and between the two there was observable a striking resemblance. In her sixteenth year this girl suffered from lupus upon her right thigh, accompanied by periostitis upon the tibiæ and forehead, which healed under the use of mercury, but returned at intervals. In her seventeenth year she married a man previously healthy, but who a short time after marriage became ill, and eighteen months later died, after being eight days in the hospital. No autopsy was made; but the death was reported as one from tuberculous meningitis. There was a child from this marriage, which was born three or four weeks before full term and died in fourteen days from general debility. The woman again married, the second husband remaining healthy; the child of this marriage, seventeen months old, although in other respects well nourished, suffered from—1, a universal lichen, presenting the appearance of lichen scrophulosorum; 2, an ulcer upon the right thigh, looking as if due to the ulceration of a syphilitic deposit; 3, an infiltration of the subcutaneous tissues of the right instep, through which could be felt some enlargements of the bones lying beneath.

From the histories of the patients composing this second group the following conclusions were drawn. 1. That the organism of the female can maintain the influence due to syphilitic infection in the most enduring manner. This influence appears, however, to interfere less with the intra-uterine life of the child; for it can come into the world apparently quite healthy; but the germ of future syphilitic disease is planted in the offspring, which may remain latent for years. The second child of the grandmother of Group 2 was born at full term, in good health, and at the age of five years, fifteen years after the infection of her mother, an eruption appeared, the connection of which with syphilis it is not possible to doubt. 2. That syphilis can in some in-

stances be inherited from the maternal side alone. The father of the younger of the two daughters belonging to this group was still living, and in good health. The two husbands of the elder sister were at the time of their respective marriages quite healthy; and although some doubt might exist as to the true nature of the disease to which the first succumbed, still in the case of the syphilitic infant its disease must be ascribed entirely to its mother, as the father was in perfect health. The third group consists of a fifth infant. The mother of this child, in February, 1871, was admitted into the hospital with syphilitic ulceration of the genitals and throat. On the third day after her admission she was delivered of a child, which died at birth. Three years previously she had borne a child which lived in full health. After a course of mercurial treatment the patient was discharged cured, as all the symptoms of syphilis had disappeared. This woman appeared a second time at the hospital two years later, and again, somewhat prematurely, was delivered of a child. The mother upon examination presented pigmented scars upon the legs, and stated that since her first discharge from the hospital she had suffered from ulcers which had been very tedious in healing. From the growth of the hair, nails, etc., the infant was seen to be nearly at full term; on the palms of the hands and the plantar surface of the feet were dark-red spots; on some of the fingers were impetiginous crusts, surrounded by an inflammatory areola; on the forefinger of the right hand was a single bulla. Along the nail of each great toe, having the form of a half-moon, was a spot upon which the skin was wanting, presenting a mummified appearance, and bordered by a line of bright-red tissue, where was apparently an inflammatory reaction. This case of congenital syphilis presented, in addition to the general eruption, a single spot of pemphigus, and especially the affection of the borders of the nails alluded to above, which, so far as is known to Professor Lewin, has not been described. The question could be raised whether the process had been dry during its whole course, or whether this condition was left after a deep-seated bulla of pemphigus, in which the process of mummifaction had followed the first state of the eruption.

The three children whose histories have been given were all vaccinated with humanized lymph; in all three the course was normal, differing in no respect from that seen in the healthy infant, and the lymph obtained from the vesicles could not by a microscopic examination be distinguished from that obtained under similar conditions from a healthy infant. This goes to strengthen the assertion that vaccination takes a normal course in children with congenital or acquired syphilis.

Treatment of Cholera.—Dr. William Henry Thayer believes that in the treatment of cholera the method which promises the greatest degree of success is the administration of calomel in frequently-repeated doses until the discharges lose their characteristic watery appearance, become green or brown, and have a fæcal odor.

Given hourly in ten-grain doses until colored evacuations are produced, its administration is attended with relief of the epigastric distress, with improvement in the pulse, and with restoration of warmth in cases which were running into the stage of collapse.

Dr. Thayer believes that the essential pathology of cholera consists in a blood-change, by which the red corpuscles lose their power of oxygenation and cause a general arrest of the circulation.

He considers it to be highly probable that calomel, acting primarily on the portal system, through the intestinal mucous membrane, relieves secondarily the congestion of the systemic capillaries, thereby arresting the destruction of the red corpuscles, while it eliminates the choleraic poison by the bowels. He concludes from his observations during various epidemics that all nourishment in the first or second stage is hurtful, as no food can be digested; that opium is useless unless at the very outset; that alcohol has no effect in restoring the warmth; that external heat is useless, the warm bath very injurious, and friction of no avail; and, finally, that as near an approach to repose as it is possible to attain, with cold affusion, moderate draughts of water or bits of ice, sinapisms to relieve the cramps, and the continued use of calomel, will give the best results possible for us to obtain. Of thirteen cases seen during the first stage, twelve were treated exclusively with calomel, and recovered, while the one not treated with calomel died.—*The Medical Record*, July 1, 1873.

Intussusception.—Dr. Affleck reports two cases of intussusception in children. 1. A child, aged seven months, generally healthy, had diarrhœa, vomiting, severe retching, and pain, which resisted ordinary remedies. On the fourth day blood passed per anum. Large enemata were at once rejected; no hernia was present; inflation of the bowel by bellows was tried without success; fluid mercury was given by the mouth, but the patient died on the fifth day. On post-mortem examination, an invagination of the ileum into the cæcum was found in the right iliac fossa. The bowel above was greatly distended; below it was pale and empty.

2. The second case was that of a child aged five months, previously healthy. In the course of a diarrhœa, a copious evacuation was followed by a sudden cry, vomiting, retching, and exhaustion; after which no fæces passed, only blood. Nothing was felt in the rectum; there was no hernia; the abdomen was soft. Enemata were at once expelled, but strong inflation with the bellows after two or three minutes *suddenly* overcame the resistance, and the abdomen became tympanitic. Vomiting ceased; a warm bath and castor oil were followed by a free evacuation, and the patient next day was quite well.—*British Medical Journal*, July 26, 1873.

The Influence of Digitalis on the Weak Heart of Typhus Fever.—At a meeting of the Medical Society of the College of Physicians of Ireland, Dr. Grimshaw reported that he had recently used digitalis extensively in the treatment of severe typhus fever, and had come to the following conclusions:

1. Digitalis does not shorten the duration of the fever or influence its characteristic range of temperature.

2. It prevents or lessens delirium, and improves the tension of the pulse, which falls somewhat in frequency during its exhibition.

3. A sudden fall in the pulse-rate and temperature is an indication of danger, and calls for the withholding of the drug.

4. Suitable doses are from half an ounce to an ounce and a half of the infusion every second or third hour, and stimulants should be given in addition if, after twenty-four hours, the digitalis has not produced beneficial effects on the pulse.—*British Medical Journal*, July 26, 1873.

Development of Bone.—Ludwig Steda (Report of the Scientific Association of Riga) has contributed an elaborate memoir on this subject. He endeavors to establish the following: Osseous tissue is formed without division of cartilage, and is a direct transformation from the connective-tissue element. Where bone is preceded by cartilage, as is the case with the long bones, it is always observed that the cartilage atrophies noticeably from the centre, thus permitting the cells of the periosteal layer to penetrate within the shaft, there to undergo true ossification.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, mdeical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 30, 1873.

EDITORIAL.

INSANITY IN ITS RELATION TO CRIME.

THERE lies on the table before us a little book* upon a subject so important and containing sentiments so extraordinary that we propose to make it the subject of an editorial notice. Although it is elegantly written, attractive and forcible in style, and holds the attention of the reader from the first to the last page, yet we deeply regret that it has been produced by a member of our profession. The modern court—the American system of criminal jurisprudence—offers day by day its farces, at which the philosopher might with equal justice laugh or cry. But it is the legal, not the medical, profession which is responsible. Whatever the theory may be, so far as our experience goes, very generally in practice the district attorney looks upon himself as the sleuth-hound set by society to hunt down: in his opinion it is not his place to separate the innocent and the guilty, but to *convict*. Often the medical expert alone stands between him and his victim, and, although honest and capable, is viewed simply as an obstacle in the way, to be cajoled, ridiculed, trapped, browbeaten, and if possible battered into oblivion. Of all the points upon which medical experts testify, no one is more delicate, no one more important, no one the subject of more abuse, than insanity, and for this very reason it becomes the professional man to speak with caution upon this subject; but we cannot refrain from expressing our astonishment that the gentleman chiefly through whose testimony, ophthalmoscopes, and paraphernalia McFarland was acquitted, should now come forward as the advocate of sentiments which would suit the most bloodthirsty Jeffreys.

It cannot be gainsaid that when public opinion is such as to justify murder under certain provocations, murder committed under such provocations will often be justified or condoned by juries upon the plea of insanity. For example, so long as society justifies a man in shooting the seducer of his daughter, so long will juries often find insane the sanest man that does such an act. But this has nothing to do with the merits of the plea of insanity. When a jury has determined to acquit the prisoner at the bar although he be guilty, excuse will not be wanting; if the plea of insanity be insufficient, some other will do as well.

Leaving out of sight these cases in which the jury simply uses the plea of insanity as an excuse for doing what it has determined upon, injustice is, we think, at least as often done in the condemnation of the insane as in the acquittal of the sane.

Like everything that comes from his pen, the book of Dr. Hammond is in many respects very able. The argument that underlies it is most specious, and, having its foundation in truth, puts on the appearance of truth. Yet in our judgment the truth is warped, distorted, mixed with fallacies until it makes an image half clay, half iron, which is but a caricature of justice. Stated briefly, the fundamental idea or argument of the book is,—the individual is nothing, society is everything; the protection of society being paramount, the liberty or life or death of the individual is as nothing when opposed to the general good; therefore, if the individual be insane, unaccountable to God, he is accountable to society, and should be punished,—punished, too, as severely as the sanest!

"Laws do not always rest—in fact, cannot always be based—upon the principles of abstract justice," says Dr. Hammond. "When necessity requires it, both law and equity are set aside, and brute force takes their place." True, in a measure: the fallacy consists in applying this to the treatment of the insane criminals, since no necessity exists for the application of extreme brute force.

"A law, therefore, may be unjust as regards an individual or a few individuals, and beneficial to society at large: it is then a good law." Granting for a moment the truth of this, the same fallacy follows its application as has just been noted. It is not necessary for the protection of society that the insane murderer should be hung. Further,—

* Insanity in its Relation to Crime. By William A. Hammond, M.D. New York, D. Appleton & Co., 1873.

although, since we have not been bred in the law, we would here tread most reverently and hesitatingly,—the conviction is strong with us that the philosophy of law put forth by Dr. Hammond is incorrect. We doubt very much whether a law that is unjust to the individual can be beneficial to society. The moment a law is distinctly perceived to be unjust, men will rise up against it and condemn it, and it can only exist as a law of terror and of military force. In a country like this, where the basis of all law is public opinion, public opinion will sooner or later overthrow such a law.

The chief example which Dr. Hammond adduces of a good law unjust to the individual we hold to be an atrociously wicked law,—not framed for the good of society, but for the good of one individual at the expense of society,—a law for the good of the despot, which, a rag of mediæval feudalism, still clings to the codes of some communities. It is "the attainder of blood," the punishing of the children for the high treason of the father. As must be eventually the fate of all such laws wherever public opinion rules, in this country this "attainder of blood" has been abolished.

The only other example adduced by Dr. Hammond as a just law good for society but unjust to the individual seems to us equally unfortunate. It is the punishing of an individual for breaking a law of whose existence he does not know. So far as criminal cases are concerned, every sane man knows what is, and what is not, a crime; and in regard to ordinances the theory is that the individual must inform himself; and we can see no injustice in punishing him for neglecting this duty.

We have no space to follow out in detail the argument of Prof. Hammond: though fair to look at, it seems to us so pieced with fallacies that, like the statue of clay and brass, it needs but to be struck in its weaker parts to totter to the ground. We can only refer to the chief among these fallacies, a constantly recurring one, *i.e.*, that society must needs hang the insane murderer to protect itself.

We have already alluded to the influences exerted by the occupation of the officers of the law to lead them into severity towards the individual. We may scarcely wonder that a judge, bred as a district attorney, or even as a member of the criminal bar, should by long habit so destroy all that sympathy which is due even to the outcast—should so far forget his sense of decorum—that, under the most solemn circumstances, when, as the instrument of the law, he is pronouncing doom, he should taunt the criminal as follows: "You have been convicted of the crime of murder. It has been alleged in your defence that you were actuated by an irresistible impulse. This may be true; but the law has an irresistible impulse to punish you; and it therefore becomes my duty to sentence you to be hanged;" or at the words of the French magistrate, "These men are madmen; but it is necessary to cure their mad acts in the *Place de Grève*."

We may not wonder, we repeat, at these sayings; but we do wonder that a physician, professedly an alienist, should quote them approvingly, and should himself write, "Looking at the matter, therefore, from a similar point of view, no valid argument can be adduced against the punishment of the insane, even though they be morally irresponsible for their acts by reason of delirium, dementia, morbid impulse, emotional insanity, or other forms of mental aberration," or the still more extraordinary sentiment, "But the individual who has a sufficient intelligence to know that pointing a loaded pistol at a human being, cocking it, and pulling the trigger, are acts which will cause the death of the person against whom they are directed, should be subjected *to the same punishment for a homicide as would be awarded for a like offence committed by a sane person.*"

We must protest against such sentiments as these of Dr. Hammond. To hang an insane man is simply to commit disgraceful, unnecessary, vengeful murder. Disgraceful, because alike at variance with Christian charity and modern science; unnecessary and vengeful, because out of it can come no good indirectly, and because it is not required for the protection of society against the individual upon whom the punishment falls.

Sequestration of the insane, the placing of them where they can do no injury, is certainly all that society needs for protection.

Society needs protection from the abuse of insanity by sympathizing juries far more than it does from the really insane criminal. A law requiring the sequestration for life of every man proved guilty of deliberate homicide, yet acquitted on the plea of insanity, would meet both difficulties at once: the sane would not escape punishment, and the insane would not be legally murdered.

Instances are not rare, and are, indeed, quoted by Dr. Hammond, in which an insane person has for weeks longed to rid himself of his life, but, having been held back by the fear of punishment for sin after death, has deliberately chosen murder, because the law would hang him for it and save him the sin of suicide,—or, recognizing the sin of murder, because he would have time to repent between

the committal of the act and the execution. What a seemly sight, to see such an insane criminal rejoicing at the gallows, thanking the sheriff and his minions for their aid in carrying out his designs! —in the wild delirium of delusion, resigning his soul into the hands of his Maker, as the law launched him into eternity.

Says Dr. Hammond, "Some of the insane are such monsters of depravity that they should be slain upon the same principle that we slay wild and ferocious beasts." Society needs protection from the smallpox, or from the pestilence. The insane murderer kills only his man,—the pestilence its thousands. The insane man is not morally responsible, has no power of choice; the pest-stricken man is not morally responsible, has no power of choice; but the latter, spreading the deadly poison, is far more the enemy of society than the former. The wild victim of hydrophobia in his madness may attack his fellows. Enemies of society, all of them. Hang them, then, on the one gibbet,—the delirious pest-stricken, the chattering insane, the tortured madman,—and call on Christian civilization, the world over, to admire with what energy society in America protects itself.

THE practical working of the theory of Dr. Hammond is seen in the case of David Montgomery, an epileptic, recently tried at Rochester, N.Y. It was proved that he was insane from recent convulsions for several days before the homicide; but, on Dr. Hammond's testimony that he was conscious at the time, he was convicted and *sentenced to be hung*. Drs. Gray and Cook testified to the familiar fact that epileptics often talk and act quite rationally for several days, being meanwhile really insane, and are afterwards entirely unconscious of what has passed, and denied the responsibility of the prisoner. This case was pending for a year and a half, the execution being postponed, until finally the prisoner became so evidently and completely demented as to require his commitment to the asylum for insane criminals at Auburn.

THE Trustees of Jefferson Medical College having requested Professor Joseph Pancoast to withdraw his resignation of the Chair of Anatomy in that institution, he has complied with the request, and will discharge the duties of the chair during the ensuing session.

REMARKS ON THE NEW CHEMICAL NOMENCLATURE.

BY W. H. H. GITHENS, M.D.

THE revolution which chemical science has undergone within the last fifteen years, and which has recently culminated in the new nomenclature, has been the result of a principle which was first recognized in organic chemistry, but which has more recently been acknowledged as applying equally to inorganic. This principle is, that in a chemical compound the arrangement of the atoms is of quite as much importance as their kind and number, and for this reason new formulæ were constructed to express this molecular arrangement.

To Berzelius we are principally indebted for the admirable system of nomenclature which is still in use in chemical science. Since his death changes have been made in details, but the general plan remains the same. By analysis and calculation he fixed the atomic weights of more substances than any other individual. Some of these equivalent numbers have been changed by later writers, and not always correctly.

At the suggestion of Sir Humphry Davy, Berzelius fixed the combining weight of oxygen at 16, of carbon at 12, and of sulphur at 32. In the case of these and a few others he was opposed by Dalton and other eminent chemists, who estimated them at one-half the value placed upon them by him: the opinions of Dalton and his friends had most weight with chemists in general, and their valuation was the accepted one.

After the lapse of years, the opinions of Berzelius were revived by Laurent and Gerhard. Careful research and comparison were made by these gentlemen, who endeavored to prove the inconsistencies of the accepted views. The principal writings of Laurent were published posthumously, and were translated for the Cavendish Society's publication for 1854.

An atom is a particle of matter which undergoes no division in chemical metamorphosis. It is the smallest particle of matter which can exist in a state of combination.

A molecule is formed when one atom unites with another atom, either different from or like itself. It is a group of atoms united by chemical affinity, and is the smallest particle of any substance which can exist in a free or uncombined state in nature. Molecules differ from one another because the atoms of which they are composed differ. They may vary in kind, in number, or in relative position.

Thus, a molecule of water differs from one of salt in the *kind* of atoms. A molecule of calomel differs from one of corrosive sublimate in the *number of chlorine atoms*. A molecule of oil of lemon differs from one of oil of turpentine in the *arrangement* of its atoms.

According to the law of Ampère, *equal volumes of all bodies in the gaseous state contain the same number of molecules*. From this law it follows that all gaseous molecules must be of the same size, and that the comparative weight of any molecule may be determined by comparing the weight of any given volume with the weight of an equal volume of a chosen standard,—hydrogen.

The molecule of hydrogen contains two atoms; when it unites with chlorine we find that equal bulks or volumes of each are required, and that the product fills the space required by the two separately. When hydrogen unites with oxygen, one volume of oxygen requires *two* volumes of hydrogen to satisfy its chemical affinity, but the product in the gaseous state occupies two volumes only, as in the previous case. When hydrogen unites with nitrogen, one volume of nitrogen requires *three* volumes of hydrogen, but the product occupies, as before, two volumes only.

These instances might be indefinitely multiplied, but they are sufficient to illustrate the fact that *compound molecules occupy double the space required by simple ones*.

The fact of the combining weight or atom of one element having the power to unite with one or more combining weights or atoms of another has called into existence a new term,—"quantivalence."

The quantivalence of an element is the expression of its combining power in hydrogen units.

With respect to this power, substances have been arranged into classes, as monads, dyads, triads, tetrads, pentads, hexads, and heptads. When the use of the adjective is necessary, atoms are called univalent, bi-valent, tri-valent, etc. Elements whose quantivalence is odd—I, III, V, VII—are called *perissads*. Those whose quantivalence is even are called *artiads*. As an element may form several compounds with the same substance, its quantivalence is not invariable; it always increases or diminishes by two; a perissad cannot become an artiad.

EXAMPLES OF VARIATIONS IN QUANTIVALENCE.

Monads	Hydrogen I.	Dyads	Oxygen II.
	Chlorine I, III, V, VII.		Sulphur II, IV, VI.
	Bromine I, III, V, VII.		Calcium II, IV.
	Iodine I, III, V, VII.		Magnesium II.
	Sodium I, III.		Zinc II.
	Potassium I, III, V.	Tetrads	Carbon II, IV.
	Silver I, III.		Lead II, IV.
Triads	Nitrogen I, III, V.	Hexads	Chromium II, IV, VI.
	Phosphorus I, III, V.		Manganese II, IV, VI.
	Arsenic I, III, V.		Iron II, IV, VI.

The *equivalent* or *atomic weight* of any substance is its relative weight as compared with hydrogen, which is considered the unit.

In order to ascertain the atomic weight, we must know—*first*, the weight of the quantity which will combine with one atom of hydrogen; *second*, the molecular weight of the hydrogen compound.

Example.—The analysis of water shows that in 100 parts there are 88.89 parts of oxygen and 11.11 of hydrogen; the ratio of 88.89 to 11.11 is 8 to 1. If the molecule of water contain only one part by weight of hydrogen, and eight parts by weight of oxygen, its molecular weight will be $1+8=9$. But each molecule may contain two, three, or more times this proportion of each ingredient. To determine this point, we recall the law of Ampère, that equal volumes of all bodies in the gaseous state contain the same number of molecules, and also the fact that a compound body will fill two volumes. Weighing one litre of hydrogen, we find its weight to be .0896 grammes; two litres of vapor of water weigh 1.6094 grammes. When we divide the weight of the water vapor by the weight of the hydrogen, $1.6094 \div .0897 = 18$, the molecular weight of steam and also of water. Thus water is shown to consist of sixteen parts by weight of oxygen, and two of hydrogen.

The atomic weight of any substance being the smallest quantity by weight which can enter into combination, by comparing the molecular weights of the various compounds of the same element the atomic weight becomes more certain. Thus, the molecule of water contains sixteen parts by weight of oxygen, a molecule of carbonic acid gas thirty-two parts, etc. In no known compound are there fewer than sixteen parts by weight of oxygen in a molecule. Thus sixteen is proved to be the atomic weight of oxygen.

In consequence of the difficulties surrounding the exact fixation of the atomic weights and the molecular composition, many errors and differences of opinion have been caused; these are now disappearing, and in the new tables we have undoubtedly a near approach to exact truth. Below are given a few of the more prominent elements:

Doubled.		*Changed but little, if at all.*	
Aluminium	27.5	Antimony	122.
Bismuth	210.	Arsenicum	75.
Calcium	40.	Bromine	80.
Carbon	12.	Chlorine	35.5
Copper	63.5	Iodine	127.
Gold	196.6	Hydrogen	1.
Iron	56.	Mercury	200.
Lead	207.	Nitrogen	14.
Magnesium	24.	Phosphorus	31.

Doubled.		*Changed but little, if at all.*	
Manganese . . .	55.	Potassium	39.
Oxygen	16.	Silver	108.
Sulphur	32.	Sodium	23.

It was the original proposition of M. Cannizarro and M. Wurtz to double the atomic weights of all the metals.

(To be continued.)

CORRESPONDENCE.

To the Editor of the Philadelphia Medical Times:

DEAR SIR,—Your recent editorial remarks under the caption of the "Wills Hospital" suggest to me the propriety of stating some facts which may avert the creation of an erroneous impression in regard to the present functions of the institution.

In the bequest of James Wills the object is stated to be for "the relief of the indigent blind and lame." Latitude given to the word "relief," in the opinion of legal counsel, permitted it to mean the medical and surgical treatment of them in the hospital that was endowed.

It would seem that the donor, in his goodness and simplicity, intended, by the indefiniteness of the wording of the will and the entire absence of details of his wishes, that the "Trustees or Managers" should have much discretionary authority in regard, as it is expressed, to "the rightful regulating of the establishment."

If the intentions of the will have not—through the force of circumstances which will be alluded to—been fully carried out, there has, nevertheless, been no perversion of the designs of the founder. The hospital has become exclusively an eye-hospital rather as the result of public demand or the necessity of patients than through active determination on the part of its managers so to render it. There has been no official action of that body excluding "lame" persons from its benefits.

The institution has been long popularly known as the Eye Infirmary, or the Eye Hospital, and, among medical men, as the Wills Ophthalmic Hospital. During the long period of my service as one of its surgeons I have never been applied to for the admission of a case of lameness; and, to my knowledge, such applications are not made. The pressure on the institution is for the admission of ophthalmic cases, and its limited wards are, unfortunately, almost always overcrowded with such patients. There is, therefore, no room for the admission of, nor, in the present financial condition, are there any means or facilities for the treatment of, the "lame."

There are also good reasons why the admission of diseases and injuries of the limbs producing lameness would be improper in the same institution with patients suffering from diseases of the eyes. Diseases and injuries of the lower limbs are frequently attended with suppuration and septic discharges which are dangerous in the vicinity of cases of eye-affections, especially of those recently submitted to important operations for the restoration of sight.

It has been exceedingly difficult, and at times impossible, to keep the wards of the Wills Hospital free from the infectious spread of inflammatory and suppurative disease; and my surgical colleagues will agree with me in the opinion that the risk of such calamitous endemics would be greatly increased by having cases of the character I have alluded to placed in proximity to ophthalmic patients.

In illustration of this incompatibility, I may recall my once having seen in the institution, very many years ago, a moribund case of complete gangrene of both legs lying in a ward with ophthalmic cases occupying beds in the vicinity. Every hospital surgeon knows the danger of the spread of germinal matter from such a case, and its liability to produce destructive inflammation of the eye.

If the Wills Hospital were to admit the indefinite class of "lame" cases, it would soon become a very small and unimportant *general* hospital in character; for lameness results from such varied causes, as organic disease of the brain, producing paralysis of a leg, or by the crippling induced by spinal caries, etc. The hospital is now resorted to by a vast number of patients requiring attention to their eyes, of whom but a comparatively small number are admitted to remain in the wards: thus the institution has reached a utility far beyond what its founder could have hoped for.

In reference to your statement that "the foundation of the Orthopædic Hospital may have been rendered necessary by the non-treatment of orthopædic cases," I may be permitted to remark that a hospital for the lame and an orthopædic hospital cannot in functions substitute each other. Orthopædic surgery covers a far greater scope than lameness, and at the same time the majority of the cases of lameness are not proper for admission to an orthopædic hospital. Orthopædic cases, such as wry neck, spinal curvature, or a clubbed hand, would not be admitted to a hospital for the lame; whilst most of the injuries and diseases that cripple the legs would be excluded from an orthopædic hospital.

I am convinced that the institution is conducted as nearly in compliance with the letter and spirit of the will *as is practicable and right.* As some restriction in the number of admissions, and discrimination in regard to their character, must necessarily be made, I think that the beneficence of the bequest will be best fulfilled, and suffering humanity gain the most, by acting on the democratic principle of "the greatest good to the greatest number," and continuing the objects of the institution as they are recognized in its conventional title of the "Wills Ophthalmic Hospital."

Respectfully,

R. J. Levis, M.D.

REVIEWS AND BOOK NOTICES.

HANDBOOK OF PHYSIOLOGY. By WILLIAM SENHOUSE KIRKES, M.D. Edited by W. MORRANT BAKER, F.R.C.S., Lecturer on Physiology at St. Bartholomew's Hospital. A new American, from the Eighth enlarged English Edition. 12mo, pp. 656. Philadelphia, Henry C. Lea, 1873.

This handbook is so well known as to require no extended notice at our hands. In its enlarged form it is, in our opinion, still the best book of physiology, most useful to the student of medicine, crowded as he is during the winter months with a multitude of varied studies. We congratulate the American publishers on having replaced the reprint of the very old edition they have so long supplied the market, by this new edition, which is fully up to the demands of modern physiology. We predict for it a continued popularity.

A REPORT ON THE ORIGIN AND THERAPEUTIC PROPERTIES OF CUNDURANGO. By W. S. W. RUSCHENBERGER, M.D. Published by order of the Navy Department, Washington, 1873.

This pamphlet of twenty-five pages contains pretty much all that is known in regard to cundurango, its natural history and therapeutic value. We agree with the author that "the testimony as to the therapeutic value of this plant is not satisfactory."

DIE ORTHOPAEDISCHE BEHANDLUNG DER POTT'SCHEN KYPHOSE von CHARLES FAYETTE TAYLOR, M.D. Aus dem Englischen übersetzt von Dr. PAUL BIESENTHAL, pract. Arzt in Berlin. Mit 20 in den Text eingedruckten Holzschnitten. Berlin, 1873.

This is a translation of a paper read by Dr. Taylor before the New York Medical Society. If any of our readers are so in love with the German as to prefer it to the Saxon, we commend this pamphlet to their notice.

RECENT IMPROVEMENTS IN OPHTHALMIC SURGERY. By D. S. REYNOLDS, M.D. Read before the Kentucky State Medical Society.

This little pamphlet contains a short account of some of the more recent operations performed for the removal of strabismus, conical cornea, and corneal opacities, with a few pages devoted to the treatment of ulcerations of the cornea, iritis, and sympathetic ophthalmia.

SELECTIONS.

CONCERNING THE CLOSURE OF ABNORMAL ANUS.

BY JOHN DUNCAN,

Assistant-Surgeon, Royal Infirmary, Edinburgh.

THE treatment of artificial anus has at various times attracted considerable attention. Till a comparatively recent date, its pathology was imperfectly understood; but the recognition of the septum as the main obstacle to closure, and the methods for overcoming that obstacle adopted by Schmalkalden, Physick, and Dupuytren, greatly elucidated the subject, and marked a very decided advance in principle and practice. Still, however, in a certain number of cases the destruction of the septum is not followed by obliteration of the abnormal orifice, and in these circumstances surgeons resort to plastic operations, of which the main characteristics are a bewildering variety and a great absence of success. I venture to add to the list yet another method, because I think it presents fewer chances of failure than any hitherto devised. It rarely falls to the lot of a surgeon to consider the treatment of a case to which such an operation may be applicable. I make no apology, therefore, for illustrating my proposal by a solitary example. It possesses at least the merit of completeness, and assuredly exhibits no undue haste on my part to anticipate the efforts of nature.

The patient was a domestic servant, aged 45, whom I was asked to see by Dr. Inglis in April, 1869. She had been ill for a week before sending for Dr. Inglis, and had supposed her illness to be a bilious attack, unconnected with the swelling in her left groin, as this had often previously come and gone without causing discomfort. I found it to be a femoral hernia, already red, swollen, and emphysematous. An incision exposed a loop of the intestine gangrenous in its entire circumference, and rent on its convex surface. I divided the stricture and left the bowel *in situ*. The patient slowly recovered with an abnormal anus capable of admitting two fingers, and through which alone the fæces were discharged.

She was advised to await a possible natural contraction of the orifice, and I did not again see her till June, 1870. In the interval she had worn a truss, which, however, retained the fæces very imperfectly, and during the whole time there had been no passage by the rectum. The artificial anus had not diminished in size, and the septum was distinct and prominent. The orifice of the lower portion of the bowel had contracted somewhat, but was large enough to admit the little finger.

Instead of using the enterotome, I passed a double silver wire through the septum, about an inch and a half above its free margin. It was left loose for two days, and then one of the wires was gradually tightened, until on the eighth day it ulcerated its way out. The other wire had meanwhile, as I anticipated, become slightly imbedded by reunion of the deeper parts, and it now fulfilled the purpose for which it had been left, in being drawn out through the recent adhesions. The same day fæces passed by the rectum, and, after a week of considerable irritation, solid motions were regularly and naturally established. The patient was sent to the country, with instructions to remove the truss only for purposes of cleanliness.

I again saw her in December, 1871, and was disappointed to find that still no contraction of the orifice had taken place, although (the truss being regularly worn) all the fæces passed by the natural route. I repeated the former operation, including in the wire nearly an inch more of the contiguous walls of intestine. The condition of affairs was not thereby improved, and it was plain that the septum was no longer an impediment to closure. In April, 1872, I therefore performed the following operation:

Having thoroughly cleared out the bowel by purgative and enema, I dissected up the mucous membrane all round the abnormal orifice for more than half an inch, invaginated it, and sewed the raw surfaces together by six points of interrupted catgut suture, which were then cut short. I next pared freely the margin of the skin, and brought it together by means of silver wire.

During the after-treatment the parts were relaxed by keeping the thigh flexed. The diet was restricted to milk with lime-water. On the eighth day, finding the wound entirely united, I removed the stitches. A little froth issued from the small openings left by the removal of a corner stitch. These openings remained patent for some weeks, notwithstanding the use of the hot wire. Nothing but gas, however, escaped from them, and they ultimately soundly healed.

The patient remains in every respect perfectly well, and it is now a year since the closure was effected.

Such an operation is, of course, only possible when the artificial anus is of large size; but it is precisely in these cases that other methods are least successful. The advantages which I claim for it are, that it presents to the fæces the normal mucous surface of the bowel, that it diminishes the strain upon the stitches, and that it largely increases the depth of raw surface, by the adhesion of which the pressure from within is to be resisted. It seems to me theoretically sound, and in this case at least was practically successful.—*London Lancet.*

GLEANINGS FROM OUR EXCHANGES.

Syphilitic Disease of the Placenta.—The *Medical Times and Gazette*, May 10, 1873, gives a summary of Dr. Ernest Fränkel's views on this subject. Dr. Fränkel's article contains the history of over twenty cases of syphilitic placenta. He summarizes his observations in the following conclusions:

1. The placenta may become affected by syphilis, and there are certain characteristic indications of this.

2. The syphilitic placenta occurs only in hereditary or congenital syphilis in the fœtus.

3. The seat of the disease varies according as the mother remains healthy and the syphilitic virus is communicated directly from the father to the ovum by means of the semen, or according as the mother is diseased. In the former case the affected fœtal villi of the placenta degenerate through proliferation of cellular granulations, with consecutive obliteration and atrophy of the vessels, complicated frequently by marked proliferation and thickening of the epithelial covering of the villi.

4. In the latter case, when the mother is syphilitic, the three following conditions may occur: *a*. The mother, through the act of impregnation, is simultaneously affected with syphilis with the fœtus; diffused syphilis of the placental villi may then develop itself, though primary infection of the maternal parts—endometritis placentaris—is not excluded. *b*. The mother becomes infected before, or shortly after, conception. The placenta may remain normal, or become diseased under the form of endometritis placentaris gummosa, or, according to Virchow, in a more limited sense, endometritis decidualis. *c*. The mother becomes infected only during the latter months of pregnancy (seventh to tenth month). It then generally happens that, in case the father was healthy at the time of impregnation, the fœtus, as well as the placenta, is exempt from the above-described alterations.

5. The infection of the fœtus on passing through the maternal passages is rare, and not yet proved conclusively.

Rupture of the Bladder from Injury—Recovery of the Patient.—Dr. J. Mengus (*Abeille Médicale*) records a case of this accident where the usually fatal result did not ensue.

At nine o'clock in the morning, a young man, æt. 34, fell on the edge of a wine-press from a considerable height; he immediately felt an acute pain in the pelvic and right hypochondriac region, but was able to walk and get home to bed. He was seen two hours after the accident, and presented the following symptoms: Pulse very slow and feeble; the right side of the belly swollen, tender, and dull on percussion; he had not passed urine since four o'clock in the morning, and could now pass only a few drops. A catheter was passed, which obtained but a few more drops, and a careful examination was made of the bladder, but no rent or opening could be ascertained. The bladder was then injected with warm water. The greater part, but not all, flowed back, tinged with blood. He was treated with opium, camphor, and quinine in pill, frequently repeated. On the same day, in the evening, the pain increased; leeches were applied over the belly; he restrained himself from drinking, as far as possible, and by the fourth week the symptoms disappeared. He could retain and urinate as before.

Chronic Tetanus treated by Excision of Cicatrix.—Mr. Annandale gives a short account of the following case: A boy, aged 16, wounded his foot. On the ninth day afterwards, trismus came on; and he came into hospital on the sixteenth day after the wound, or the seventh of the trismus. There was no laryngeal symptom nor opisthotonos. The patient swallowed well; his bowels were freely opened by croton oil, and for three days he was kept under the influence of small doses of morphia. For two days more he had ninety grains of chloral daily. On the twelfth day of the tetanus, slight contraction of the muscles of the limb began. On the next day, the cicatrix and a piece of nerve which appeared congested were cut out, and all medical treatment stopped. There was no improvement for two days; but on the third day, or sixteenth of the disease, he began to improve, and went out soon, quite well.—*British Medical Journal*, July 26, 1873.

Galvanism in Post-Partum Hemorrhage.—The following case may be considered of interest as furnishing an instance of the efficiency of a mode of treatment for the great opprobrium of obstetric art, which, if not new and little known, is at any rate far from being so widely employed as its numerous advantages would appear to indicate it should be.

The patient was in an extremely feeble state of health, and subject to epileptiform seizures. Convulsions came on during the first stage of labor, and could only be checked by keeping her under the influence of chloroform for some time. Failure of uterine action occurred before the os uteri was fully dilated; but, as it was sufficiently dilatable, forceps (Beattie's) were introduced, and delivery was accomplished. Still, the uterus did not contract, and, after the placenta was removed, hemorrhage could only be restrained by keeping the hand within the uterus. Grasping and kneading the uterus, cold affusion externally, and injections of cold water per vaginam, produced no effect. A dilute solution of perchloride of iron was freely injected into the uterus, but proved ineffectual. The employment of galvanism was then suggested as a *dernier ressort*, and one of Stöhrer's portable coil machines was procured. An interrupted current of considerable intensity was directed through the uterus, one pole of the battery being applied to the abdominal walls immediately over the fundus, by means of a curved plate of copper, and the other placed in the cervix. Almost immediately firm contraction took place; and when the current was discontinued after a short time, the uterus remained securely contracted, and no further hemorrhage took place. The patient made a good recovery.—*British Medical Journal*, August 9.

Oxide of Zinc in Infantile Diarrhœa.—In the *British Medical Journal* of July 12, Mr. Edward Mackey, M.B., recommends oxide of zinc in infantile diarrhœa, especially in those forms complicating nerve-troubles or hooping-cough. He points out that it has "tonic and anti-spasmodic as well as astringent qualities, a combination in a non-irritant substance exactly suited to many cases of the malady." It does not irritate, as chalk sometimes does, or gripe, as acids do occasionally, and is a better nerve-tonic than bismuth. Mr. Mackey says that it has given him excellent results in all varieties of infantile diarrhœa, in conjunction with

suitable diet. Dose, one grain for any age under two years, with a little syrup, mucilage, and dill-water three or four times daily, not on an empty stomach. A larger dose may nauseate. He says that oxide of zinc will give us in many cases the maximum of good with least liability to harm,—an advantage to be desired, especially in out-patient and distant cases. Dr. Waring-Curran has referred to this use of oxide of zinc, in the *Lancet*, October, 1868, and Dr. Brakenridge, in the *Medical Times and Gazette*, February, 1873, points out its tonic and anti-spasmodic as well as astringent properties.

Cholera Infantum.—Dr. Edward R. Palmer says (*The American Practitioner* for August), "Previous numbers of *The Practitioner* have contained articles highly commendatory of the calomel and of the bismuth and pepsin treatment of cholera infantum. I have tried both, and am fully convinced of their inferiority in this disease to the creosote and lead treatment. In the treatment of a large number of cases during the last three summers, but one has proved fatal, and that one was in a state of complete collapse before it was seen. The formula used is as follows:

℞ Mucilaginis acaciæ, ℥ss;
Liquoris calcis, ℥iss;
Creosoti, gtt. iij;
Plumbi acetatis, gr. xvj.
S. A teaspoonful every one to three hours.

"One thing proved is the innocuousness of the acetate, no symptom of lead-poisoning having in any instance resulted. A former professor of chemistry in this city was in the habit of asserting that sugar of lead might be given in scruple or half-drachm doses without any toxic effect, which seems, though contrary to general opinion, exceedingly plausible.

"Egg-water—the white of one egg to each gobletful—is given in conjunction with the above treatment. By adding a good-sized pinch of bicarbonate of soda to each glassful, the retention of this drink by the stomach is almost assured.

"Finally, in the above, reference is had to those cases only which are strictly cholera infantum, entero-colitis being excluded as a disease which during its protracted course usually needs a variety of treatment. Here too, however, creosote and lead will give great satisfaction."

Consumption of Spirits.—In the first quarter of the year 1873, duty was paid on 6,877,953 gallons of home-made spirits for consumption as beverage in the United Kingdom, being an increase of 684,051 gallons over the quantity in the corresponding period of the preceding year, or upwards of 11 per cent. In England the quantity was 3,790,712 gallons, an increase of 386,838 gallons; in Scotland, 1,466,124 gallons, an increase of 157,228 gallons; in Ireland, 1,621,117 gallons, an increase of 139,985 gallons. In the same period 1,325,360 proof gallons of imported rum were entered for consumption in the United Kingdom, an increase of 275,236 gallons; 951,163 proof gallons of imported brandy, an increase of 71,814 gallons; and 246,810 proof gallons of other imported spirits, not sweetened or mixed, being an increase of 70,029 gallons.

Subcutaneous Carbolic Injections in Intermittent Fever.—M. Déclat, at a meeting of the Academy of Medicine (*Gazette Médicale*, December 28), stated that in cases of intermittent fever he makes, on the first day of treatment, four subcutaneous injections of 100 drops of a one per cent. solution of carbolic acid, the next day three, the third day two. The first operation, says the author, always diminishes the fever, and sometimes cures it; the second is sometimes a work of precaution; and the third is so almost always.

Belladonna in Intestinal Invagination and Hernia.—M. Gallicie (*La France Médicale*), in a paper on belladonna, says it is the special medicament for intestinal invagination, strangulated or not, as also for strangulated hernia. It acts on both the spasmodic and inflammatory elements. In both cases, however applied, its first effect is to alleviate the intensity of pain, and to diminish and arrest the vomiting.

MISCELLANY.

Transfusion of Blood (*Pepys's Diary*).—Under date of November 21, 1667, we find: "With Creed to a Tavern, where Dean Wilkins and others: and good discourse; among the rest, of a man that is a little frantic (that hath been a kind of minister, Dr. Wilkins saying that he hath read for him in his church), that is poor and a debauched man, that the college have hired for twenty shillings to have some of the blood of a sheep let into his body; and it is to be done on Saturday next. They purpose to let in about twelve ounces; which, they compute, is what will be let in in a minute's time by a watch." November 30, we have the sequel: "I was pleased to see the person who had his blood taken out. He speaks well, and did this day give the (Royal) Society a relation thereof in Latin, saying that he finds himself much better since, and as a new man; but he is cracked a little in his head, though he speaks very reasonably and very well. He had but twenty shillings for his suffering it, and is to have the same again tried upon him; the first sound man that ever had it tried on him in England, and but one that we hear of in France." November 14, 1661, I find: "Dr. Croone told me that at the meeting at Gresham College to-night there was a pretty experiment of the blood of one dog let out (till he died) into the body of another on one side, while all his own run out on the other side. The first died upon the place, and the other very well, and likely to do well. This did give occasion to many pretty wishes, as of the blood of a Quaker to be let into an archbishop [e. g., Laud?], and such like; but, as Dr. Croone says, may, if it takes, be of mighty use to man's health, for the amending of bad blood by borrowing from a better body."

Specialities.—Dr. Robert Barnes says, "I have recently been honored by a visit from a lady of typical modern intelligence, who consulted me about a fibroid tumor of the uterus; and, lest I should stray beyond my business, she was careful to tell me that Dr. Brown-Séquard had charge of her nervous system; that Dr. Williams attended to her lungs; that her abdominal organs were intrusted to Sir William Gull; that Mr. Spencer Wells looked after her rectum; and that Dr. Walshe had her heart. If some adventurous doctor should determine to start a new speciality, and open an institution for the treatment of diseases of the umbilicus,—the only region which, as my colleague, Mr. Simon, says is unappropriated,—I think I can promise him more than one patient."—*London Lancet.*

CLAY-EATERS.—The Agmara Indians, inhabiting the shores of Lake Titicaca and the lofty plateau of the Andes, find the struggle for existence hard, at an altitude of more than 11,000 feet above the sea-level. Their principal articles of food are *quinoa*, a coarse grain resembling rice, and potatoes, of which tuber their country is the original home. The difficulty of boiling food at so great an altitude necessitates the previous maceration of all articles intended to be so cooked. The potato is, therefore, prepared for storing and use by exposing it to the frost; then it is placed in water, and stamped into a paste; all the soluble matter is washed out, and the starchy and farinaceous substance alone remains. This is called *chuno*, and it is made into a nutritious though insipid soup. The Agmaras use clay as an article of food, mixing it with *quinoa*. The clay they use is of a whitish color, and rather gritty. Careful analysis shows that it contains no organic matter; and therefore it must be used merely for the purpose of producing a satisfactory though delusive distention of the stomach.—*Popular Science Monthly*.

THE following curious statement comes to us on reliable authority: A vicious horse (gelding) that had the singular habit of striking violently with his fore feet, especially when being shod, was for several years worked with a mare that during the time bore a colt. This colt, when quite young, developed the habit peculiar to its mother's mate, becoming violent when any attempt was made to handle its fore-limbs. The habit increased with the colt's age, and, on being shod the first time, its manner of striking was observed to be precisely like that of the horse. The mother of the colt was unusually kind and gentle.—*Popular Science Monthly*.

PORTABLE DRY INK.—At a recent meeting of the Frankfort Polytechnic Association, Professor Boettger exhibited a novel kind of ink, which is admirably adapted to take on journeys and exploring expeditions. White blotting-paper is saturated with aniline-black, and several sheets are pasted to form a thin pad. When wanted for use, a small piece is torn off and covered with a little water. The black liquid which dissolves out is a good writing-ink. A square inch of the paper will give enough ink to last for considerable writing, and a few pads would be all that an exploring party need carry with them. As water is always available, the ink is readily made.—*American Journal of Pharmacy*.

THE RAISING OF CHILDREN DOUBLED.—Dr. Farr reports that the proportion of children raised has doubled within a hundred years. In London, the proportion of deaths under five years was—1730 to 1749, 74.5 per cent.; 1770 to 1789, 51.5 per cent.; 1851 to 1870, 29.8 per cent.—*The Medical Examiner*.

IMPORTANT, IF TRUE!—Acording to the *Indian Gazette*, the well-earned distinction of Rai Bahadoor has been bestowed upon Baboo Kannaye Lall Dey.

CHLOROFORM.

AIR.—"Spirito gentil nei sogni miei."—DONIZETTI: *La Favorita*.

Spirit genteel,
Sweet chloroform,
Soft o'er me steal,
Quell each alarm;
When thy soft murmur
Rings in my ears
Quickly 'twill conjure
Away all my fears.
When on my hotly-burning shoulder
Carbuncle blazes like a fire,
When through my largest three-fanged molar
The toothache rages dire,
Ah me! Ah me!
Spirit genteel,
Sweet balmy gale,
What can I feel
When thee I inhale?
For Nasmyth's big forceps with crashing claw,
For Syme's silver pocket-case, don't care a straw.
Nasmyth may wrench me with forceps or with key,
Syme may make his crucial through me—all's one to me.

From "*Nugæ Canoræ Medicæ: Lays by the Poet-Laureate of the New Town Dispensary*."

CINCHONA cultivation in Darjeeling is progressing favorably. Last year the Pomong garden, which is described as a commercial enterprise, yielded 36,000 lbs. of dry bark, and this season it will produce 50,000 lbs. A moderate estimate gives the produce of dry bark in the next three years at 200,000 lbs., calculated to yield 6000 lbs. of quinine and 6000 lbs. of other valuable alkaloids. "Fever-stricken Bengal," says *The Times* correspondent, "with its swamps and malaria, will hail the boon."

SCIENCE AS KNOWN TO THE ANCIENTS.—In Egypt mummies have been found with teeth filled with gold, and in Quito a skeleton has been discovered with false teeth secured to the cheek-bone by gold wire. In the museum at Naples, among some of the surgical instruments discovered at Pompeii there is a fac-simile of Sims's speculum. In the ruins of Nineveh, Layard found several magnifying glasses.—*New York Medical Record*.

THERE is in Cayenne a fly, called the *Lucilia Hominivorax* (man-eater), which commits great havoc among the convicts sent out to that colony by the French government. M. Charles Coquerel says that this fly lays its eggs in the mouth or nostrils of a sleeping convict, especially a drunken one, and that the offspring in their larval state usually bring about the death of their victim.—*Popular Science Monthly*.

MOULD ON BREAD.—Messrs. Richard and Legros express the belief in *Comptes-Rendus* that this frequent parasitic vegetation is due rather to the poor quality of the flour, or to bad management, than to the presence of germs in the air; and that it may be prevented by adding an excess of salt to the bread.—*American Naturalist*.

ONE profession (says *Punch*) is safe from the invasion of woman. She may enter the army, but it is impossible that she can man the navy.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF LIGATION OF THE COMMON CAROTID ARTERY, FOR THE RELIEF OF AN ENCEPHALOID TUMOR ON THE HEAD.

Delivered at the Jefferson Medical College.

BY PROF. PANCOAST.

Reported by FRANK WOODBURY, M.D.

GENTLEMEN: This young man of eighteen is in a truly deplorable condition. He is brought to us by his father, from the interior of the State, hoping that we may be able to devise means of relieving him of this immense tumor, or at least of rendering his existence more tolerable and of prolonging his life. The tumor involves, or rather projects from, the entire right side of the head. The right eye is closed and the ball drawn upward and outward; the ear is distorted; while the prominent, pulpy mass of the tumor is discharging profusely offensive, unhealthy pus, and occasionally bleeds freely from its ulcerated surface.

A clerk in a country store, he possessed excellent health until seven months ago, when he noticed a small swelling under the temporal fascia, for the appearance of which he could assign no cause. This rapidly developed into a tumor as extensive as the temporal fascia itself, and is still enlarging. A large mass was removed from this region, a short time ago, by a good country surgeon, but without controlling the development of the tumor or arresting its growth.

This is a specimen of the encephaloid or cerebriform tumor, known commonly as children's cancer, having rather less vascularity than the ordinary fungus hæmatodes. This variety of malignant growth rapidly attains great bulk, the cell-activity, as regards rapid-developing power, resembling that of the human ovum. Towards the end, the vessels attain a large size, but not ordinarily so great as in fungus hæmatodes, in which the veins may, in some of the worst cases, become half the size of the little finger. These enlarged veins are apt to burst, giving the name of bleeding cancer to the tumor, and causing hemorrhages that sometimes can only be checked by the use of the actual cautery. The etiology and pathology of these affections are very obscure and unsatisfactory, but the morbid elements are supposed to be the white blood-cells abnormally developed. These are very numerous, and thus enlarged form mother-cells, which, bursting, release a progeny of nucleated cells possessing enormous vital energy, which rapidly increase in size and become mother-cells in their turn, getting their full development in the most malignant cases probably in one or two days. By the repetition of such processes we see how the monstrous growth of these diseases *may* be explained. These tumors sometimes attack the periosteum of the orbit, rapidly involving and protruding the proper structures of the eye and eventually destroying life. They may attack the mammary gland, especially after an unsuccessful attempt to remove a scirrhous mass; but their favorite seat is in the periosteum anywhere, even the dura mater of the skull, but especially about the thigh-bone, shoulder, or sternum. You saw in this room, a short time ago, a case in which we amputated at the shoulder-joint, on account of a large tumor of this kind commencing in the periosteum at the upper end of the humerus.

The tumor in the case before us is steadily increasing in size, has become of late the seat of a violent, throbbing pain, and there is increasing hemorrhage from its ulcerated surface. The patient, recently, has also had strong convulsions on several occasions. As he is now well rested from his journey, and has been otherwise carefully prepared for the operation, I will to-day ligate the right primitive carotid artery, not in the expectation of curing the disease, but in the hope that by cutting off the supply of blood from the tumor we may decrease the rapidity of its growth, prevent or diminish the convulsive paroxysms, reduce the tendency to hemorrhage, and thus prolong the patient's life. Such cases offer the surgeon a narrow line of duty: on one hand, he sees the possible dangers that may ensue upon the operation,—the usual risk of hemorrhage from the ligation of large vessels, to which is added the danger of serious injury to the brain from the sudden diminution of its blood-supply; while on the other hand he looks to the prospect of relief, and is inexcusable if he neglects to operate when the case requires it. On account of the free anastomosis in the circle of Willis, the cerebral vessels, after this operation, usually soon accommodate themselves to the altered circulation, and the nutrition of the brain is, generally, not materially impaired. Indeed, both the primitive carotids have been ligated within an interval of one or two days, followed by the recovery of the patient, in some recorded cases; but, if they were to be tied in quick succession, fatal syncope might be expected from such a grave disturbance of the cerebral circulation. In old persons paralysis might result from the ligation of only one of the trunks, manifesting itself suddenly, or produced gradually by softening of the brain from impaired nutrition; for in them the capillary vessels are weakened and often diseased, and are unable to establish the collateral circulation as readily as in younger persons.

In tying this artery the surgeon should not stand above the head of his patient, but at the side; for, as he naturally works towards himself, he would, in that position, be likely to place the ligature too high up. The danger of bleeding, after the ligature comes away, is not from the *cardiac* extremity of the divided vessel, because the trunk, having no branches, is soon filled with a solid coagulum, but from its *distal* side; and the nearer to its point of bifurcation that this artery is tied, the greater is the danger of a recurrent hemorrhage, which sometimes diffuses itself in a sheet between the cervical

muscles. Nor should the ligature be placed too low; because the vessel is there covered by three layers of muscles, and, on the left side, by the internal jugular vein.

The point most favorable for the operation (which, as the patient is ready, I will now perform) is on a line with the middle part of the larynx. The external incision passes along the inner edge of the sterno-mastoid muscle to the middle of the neck. Taking up and dividing each layer of fascia on the grooved director, and separating the muscles, the sheath of the vessels is seen, with the descendens noni nerve running obliquely inwards upon its outer and front surface. We now raise the sheath a little with the forceps, and open it on the inner side; the artery is then gently loosened in its sheath, on either side, with the grooved director. The director is then passed from without inwards under the vessel, and the ligature passed, with an eyed probe, along the groove and around the artery. I did not see either the pneumogastric nerve or the jugular vein, nor did I desire to. (The operation was done in a little less than three minutes.)

In those cases in which the surgeon finds that the trunk bifurcates lower down than usual (as it does in people with long necks), he should seek a lower point by extending his incision downward, or, if this is impracticable, either ligate both branches separately, or tie only the one which by compression seems to influence the circulation in the morbid growth.

Seventeen days after the delivery of the above, Prof. Pancoast brought the man again before the class, read the following extracts from his note-book, and remarked as given below:

"(Three days after the operation.) The throbbing pain has entirely disappeared from the tumor, and the patient has had no convulsions or subsequent hemorrhage. He lives on beef-tea and milk, and feels much better since the operation.

"(Fourteenth day.) The ligature came away on the tenth day, the wound has healed, and he has had no hemorrhage. The tumor is much smaller from the lessened supply of blood, and is free from beating pain."

"The marked improvement that has taken place in this case, gentlemen, encourages me to still further attempt the reduction of the tumor by inducing part of it to slough away. Sir James Paget, of London, employs arrows of soft wood dipped in melted chloride of zinc paste; these are inserted, radiating towards the centre of the tumor at the line where you wish to establish the plane of demarcation. For this purpose, however, I prefer a mixture of one part of chloride of zinc with four of wheat-flour, made with water into a dough, from which little spears with barbed heads are cut, and afterwards dried. Having prepared a number of these, openings are made in the tumor with the bistoury and the arrows inserted, being retained by the barb on the head. Having girdled the tumor with these, we may expect to detach a large slough. While waiting for separation, the surface may be dusted twice daily with carbolated lime, to allay the fœtor. We have used this preparation upon it for some days with considerable advantage."

(The patient shortly after returned to his home with the tumor diminished in size nearly one-half, and comparatively free from suffering.)

ORIGINAL COMMUNICATIONS.

PHYSIOLOGICAL ACTION OF THE BROMIDE OF POTASSIUM.

BY DR. H. C. WOOD, JR.,

Clinical Lecturer on Diseases of the Nervous System at the University of Pennsylvania.

BROMIDE of potassium administered to frogs in minute doses produces as a first result a tetanoid condition, in which there may be very marked opisthotonos. After a short time this stage of muscular excitement gives way to one of great muscular relaxation and total abolition of reflex actions. Voluntary movements, however, often occur during this period, and the frog, which has been lying limp and apparently dead, will startle the observer by a sudden vigorous leap. This fact has been so frequently witnessed* that there can be no doubt of its truth.

Very early in the paralytic stage the respiratory movements are affected, and they gradually grow less until their final arrest. When a very large dose of the bromide is given, death may be induced by paralysis of the heart;† but after a small toxic dose this viscus continues beating long after the cessation of breathing. If the drug be given by an injection practised in the vicinity of the heart, sudden cardiac arrest always occurs.

Upon mammals‡ the bromide acts very much as upon frogs, inducing progressive paralysis, depression of temperature, and death by asphyxia when given in small poisonous doses, and great disturbance of the circulation with finally diastolic arrest of the heart when very freely administered.

When a solution of the bromide is applied locally to the heart, it produces instantly marked lessening of its action, and, if in sufficient amount and concentration, even instantaneous diastolic arrest.§ Upon the voluntary muscles it acts in a similar manner when similarly applied. If its solution be not too concentrated or abundant, however, the muscle of the frog is first thrown into a tetanic spasm;‖ and Dr. Purser suggests that the tetanic symptoms seen in the frog poisoned by the bromide of potassium are due to this action on the muscles. On the nerve-trunks and also on the nerve-centres the bromide acts when applied locally as it does upon the muscles.¶

* The following observers have noted this persistence of voluntary movements: J. M. Purser, Dublin Journal of Medical Sciences, xlvii. p. 324, 1869; Lewisky aus Kazan, Virchow's Archives, xlv. p. 191, 1869; J. V. Laborde, Archives de Physiologie Normale et Pathologique, t. i., 1868, 423, and Comptes-Rendus, t. lxv., 1867; MM. Martin-Damourette et Pelvette, Bulletin Thérapeutique, lxxiii., 1867, 249.

† Albert Eulenberg and Paul Guttmann, Virchow's Archives, xli., 1867.

‡ Bulletin Thérapeutique, lxxiii. 256; Virchow's Archives, xli. 97.

§ Virchow's Archives, xli. 101.

‖ Dublin Journal, xlvii. 325.

¶ Bulletin Thérapeutique, lxxiii. 253, 290; also Dr. Amory, The Physiological and Therapeutical Action of the Bromide of Potassium, Boston, 1872, Part II., p. 147.

In general poisoning by hypodermic injection of the bromide this local action is often very manifest, and paralysis of the part into which the solution has been thrown follows very rapidly upon the injection.

It is, therefore, evident that the bromide of potassium in sufficient quantity is a deadly poison to all the higher animal tissues. To therapeutists, however, the interest centres about its action when exhibited in doses just sufficient to take life, or in still smaller quantities.

The persistence of voluntary movement in the frog after the abolition of reflex actions shows that the influence of the drug is not chiefly exerted upon the cerebral centres of motor impulse, nor upon those cells of the cord which originate movement, but upon either the afferent nerves or upon those portions of the cord which transmit the impulse from these nerves to the cells presiding immediately over motion. This is confirmed by some experiments of Lewisky, in which it was found that previous separation of the cord from the cerebrum had no influence upon the action of the bromide. Both he and Purser also found that death occurred from small doses before the motor-nerve trunks and the muscles had lost their irritability.* This being so, the question arises whether the paralysis be spinal or due to paralysis of the peripheral afferent nerves. There is an apparent conflict in the evidence upon this point. Eulenberg and Guttmann (*loc. cit.*, p. 103) found that when access of the poison was prevented to one or more limbs by tying the arteries, reflex actions were abolished in these parts as rapidly as in others. Similar results have been obtained by Lewisky, by Roberts Bartholow,† by Purser‡ (*loc. cit.*, p. 326), and by Laborde (*loc. cit.*, p. 434). The latter observer has also found that electrical stimulation of a nerve high up will cause violent spasms in the muscles directly supplied by it, when it is unable to excite the slightest reflex tremor. On the other hand, Damourette and Pelvette assert a contrary result. Unfortunately, they do not give the details of their experiments. They state, however (p. 247), that if the lumbar plexus of vessels be tied before the poisoning, the fore-feet lose their reflex activity before the hinder. There are two possible methods of reconciling their results with those of the other observers. In some way the operation may have interfered with the circulation in the lower part of the cord, and consequently the poison have reached more freely the upper part of it and acted first upon it. Again, if the injection was, as is very probable, thrown into the anterior portion of the body, the poison may have reached the anterior extremities in so concentrated a form as to have acted as it were locally upon their nerves and muscles. The same observers in another portion of their memoir show that the solutions of these salts travel by imbibition; and this and their local action seem to me to be the cause of the differences of experimental results. It seems well established that cutaneous anæsthesia in greater or less degree accompanies the loss of reflex activity; for, as Dr. Purser says, a poisoned animal quite able to jump submits to pinching, pricking, burning, etc., without moving. Eulenberg and Guttman have noticed the same thing in some rabbits. Damourette and Pelvette (*loc. cit.*, p. 247) have noticed a condition in which electrical stimulation of a nerve-trunk produced marked reflex action although no excitement of the skin supplied by the afferent fibres of the nerve was capable of doing this, showing that the extremities of the sensitive nerves are affected before the trunks.

The evidence is, I think, sufficient to prove that bromide of potassium affects all parts of the nervous system of the lower animals, but that the cerebrum, the motor tract of the cord, and the efferent nerves are the last portions to be affected; that the most sensitive to its action is the receptive portion of the cord,—that which receives and transmits reflex impulses,—and next to this and perhaps almost equally susceptible with it are the peripheral ends of the afferent nerves.

Upon the cerebrum of the higher animals the bromides undoubtedly exert an influence; but I am not cognizant of any researches sufficiently elaborate to show its extent or nature.

It is well established that large toxic doses of the bromide exert a direct paralyzing action on the heart, lessening both the force and frequency of the beat, and finally causing diastolic arrest. Dr. J. G. Schouten§ found that during the slow injection of a two per cent. solution into the vena cava of a rabbit the cardiac systole grew slower, the diastolic pauses longer, and finally the heart stood still, exhibiting only fibrillary contractions of its walls. The same observer is, so far as I know, the only one who has made manometrical studies of the action of small doses of the drug. He found that such amounts of the bromide administered hypodermically or by the stomach always produced increased pulse-frequency with lessened arterial pressure. His experiments were, however, not carried far enough to demonstrate either how these two changes are brought about, or the relations of the drug to the vaso-motor nerves. Much has been predicated upon the theory which asserts that bromide of potassium causes vaso-motor spasm. No decisive proofs have, however, yet been offered of the truth of this favorite dogma. The evidence so far brought forward is as follows. Lewisky found that if the toes of two frogs—one poisoned, the other not—were cut off, the unpoisoned frog bled much more freely than the other. This experiment has been confirmed by Dr. Amory; it, however, evidently does not prove the existence of vaso-motor spasm, but only of a lessened activity of the circulation, which may be of cardiac origin.

According to Damourette and Pelvette (*loc. cit.*, p. 249), when the interdigital membrane of the frog is watched during poisoning there is seen at first very often an exceedingly brief period of increased cir-

* Confirmed by Saisson, Schmidt's Jahrbücher, Bd. cxliii. p. 17.

† Bromides: Their Physiological Effects. Providence, 1871.

‡ From the wording of his memoir, it is, however, doubtful whether Purser performed the experiment himself.

§ Archiv d. Heilk., xii. 2, p. 97, 1871; Schmidt's Jahrbücher, Bd. cliv. p. 11.

culation, but in a very short time the latter becomes much slower. Dr. Meuriot* asserts that it can readily be seen by the aid of the microscope that this slowing of circulation is due to a contraction of the capillaries, and especially of the small arteries, whose lumen may even be obliterated. Dr. Saisson† also asserts that he has witnessed a similar phenomenon in the tongue of the frog, and Dr. Hammond and Dr. Amory state that they have seen it in the brain of the dog. On the other hand, Dr. Purser (*loc. cit.*) and Dr. F. B. Nunneley‡ assert that the vessels in the frog's web are not affected by bromide of potassium given hypodermically.

My own studies of the action of various poisons upon the vessels of frog's web have yielded such varying and unsatisfactory results as to make me hesitate in accepting evidence of this nature unless otherwise corroborated. In the absence of manometrical studies, I think the most that can be fairly claimed is that our present knowledge renders it somewhat probable that the salt under consideration is capable of producing vaso-motor spasm. The further deduction that the nervous symptoms induced are secondary to and produced by this spasm is wholly gratuitous, unproven, and improbable. The action of the bromide when applied locally to the bared nerve demonstrates that it acts directly upon nerve-tissue. Further, the absolute anæmia of the bloodless "salt frog" produces no such nervous symptoms as does even a non-toxic dose of the bromide; and the direct experiments of Dr. A. Weil§ have shown that in the frog the complete abolition of circulation has no effect upon the spinal marrow during the first half-hour. The proof is very strong that the drug acts directly upon the nervous tissues.

In warm-blooded animals, toxic doses of the bromide of potassium lower very decidedly the temperature. Although the point cannot be considered at all settled, it is probable that this lowering of temperature is due to a direct checking of tissue-changes. Dr. J. H. Bill‖ has found a constant decrease in the amount of carbonic acid eliminated after the ingestion of the salt. In his experiments the daily excretion of urea was not perceptibly affected; but Dr. Rabuteau found it slightly lessened,¶ as did also Dr. Bartholow (*loc. cit.*, p. 11).

When the blood is charged with the bromide, the salt probably escapes with all the secretions. It has been found by Voisin, Amory, Namias, Bill, etc., in the saliva and in the urine. Amory has also demonstrated its presence in the perspiration. In the body of a man who died whilst taking it, M. Namias** found it in all the liquids, as well as in the brain, liver, spinal cord, lungs, etc.

Elimination takes place to a certain extent through the skin, and to some extent through the intestinal mucous membrane also. Dr. Bill (*loc. cit.*, p. 25) always detected it in marked quantities in the fæces of men taking it; and H. Quincke†† found that when forty grains of the bromide of sodium were given to dogs with intestinal fistula, two and a half hours afterwards the intestinal juices were free from the bromides, which reappeared in from three to six hours. The salt escapes also through the kidneys. The rapidity of elimination seems to vary: thus, Amory recovered one-half of the amount ingested during the first and one-third during the second twenty-four hours, whilst Bill was not able to get more than one-eighteenth of it during the first day. Dr. Bill has frequently found the bromides in the urine two weeks after the last dose has been exhibited; and Dr. Rabuteau has seen its presence persist under similar circumstances for a month.

No case of acute poisoning with the bromide of potassium has been reported, and I have never seen a single dose of it produce any obvious effect; the results of the continuous employment of large doses of it, however, demonstrate that it acts upon man as upon the lower animals. When it is taken with sufficient freedom to accumulate in the system, a conjunction of phenomena known as *bromism* arises. The cerebral symptoms are a sense of mental weakness, heaviness of intellect, failure of memory, partial aphasia, great somnolence, and depression of spirits. With these there may be decided impairment of the sensibility of the mucous membranes and of the skin, so that titillation of the fauces may be without effect, and according to Puche even heat applied to the skin calls forth no complaint, and Huette‡‡ has seen in some cases absolute anæsthesia of the sclerotic conjunctiva. The sexual function is abolished. There is also very generally fetid breath, and an eruption of acne, which may indeed be very severe. Of course, in any individual case of bromism many of these symptoms may be wanting; but when the use of the remedy is persisted in, they all become developed in an intense degree. Professor Edward H. Clarke thus speaks of a case which came under his notice: "The fetid breath becomes nauseous; œdema supervenes on congestion of the uvula and fauces; the whispering voice sinks into aphonia; sexual weakness degenerates into impotence; muscular weakness becomes complete paralysis; reflex, general, and special sensations disappear; the ears do not hear, or the eyes see, or the tongue taste; the expression of hebetude becomes first that of imbecility, then that of idiocy; hallucinations of sight and sound, with or without mania, precede general cerebral indifference, apathy, and paralysis; the respiration, without the stertor of opium or alcohol, is easy and slow; the temperature of the body is lowered; as the bromism becomes more profound, the patient lies quiet in bed, unable to move or feel or swallow or speak, with dilated and uncontractile pupils, and scarcely any change of the color of his skin or face."

It is evident that upon man the bromide in large doses acts as a depressant, which, although affecting

decidedly the circulation, acts especially upon the nervous system, depressing the cerebral functions, lowering the reflex excitability of the cord, and paralyzing the peripheral ends of the afferent nerves in the same order and degree as it does in the lower animals.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. MORTON.

Reported by WILLIAM BARTON HOPKINS.

SUCCESSFUL HERNIOTOMY IN A CHILD OF TWENTY-EIGHT MONTHS.

L. A., æt. 2 years and 4 months, was admitted to the hospital in the evening of the 7th of July, 1873, with strangulated inguinal hernia on the right side. The hernia was congenital, and nothing had been done for its relief until six weeks previous to his admission, when a truss was applied, and it remained reducible until July 5, when he fell down-stairs, and on the 6th marked symptoms of strangulation presented themselves. On the 7th restoration was attempted, but unsuccessfully, when he was brought to the hospital, verging on collapse, very pale, with quick feeble pulse, constant sick stomach, and general prostration.

On examination, a scrotal tumor was found on the right side, very tender to the touch, with considerable abdominal swelling.

After etherization, taxis having failed to reduce the intestine, the ordinary operation was performed by Dr. Morton at 6 P.M. on the same day. A large piece of intestine was found in the scrotum, of a dark maroon color, and firmly constricted at the internal ring, which was found to be very small. It was impossible to reduce the mass by pressure alone, but, after careful and steady dilatation with the finger at the ring, the parts yielded, and the intestine was then replaced.

Five deep silver sutures, clamped with shot, held the parts in good apposition; quarter-grain opium suppositories were administered with teaspoonful doses of brandy every two hours, and a liquid nourishing diet.

The symptoms subsided immediately; rapid convalescence followed, and the child was discharged, quite well, July 19, twelve days after the operation.

Strangulated hernia in subjects so young must be rare. The youngest case requiring operation, on the records of the Pennsylvania Hospital, it appears, was a lad aged 13, who was admitted March 13, 1872, the strangulation having existed for four days before; he was operated upon on the day of his admission, and was discharged, cured, April 17, 1872.

Dr. Morton believes that in these cases there is no necessity for dividing the edges of the ring, dilatation with forceps or the finger, as in the case described, being quite sufficient.

BELLEVUE HOSPITAL, NEW YORK.

NOTES OF TREATMENT.

BRIGHT'S DISEASE.

IN this affection diuretics are employed, a favorite prescription on one division being,—

℞ Potass. bitart., ʒiv;
Inf. digitalis, ʒiv. M.
S.—ʒij—ʒiv t. d.

On another division a case is being treated by the administration of large quantities of water,—about six pints being given in twenty-four hours. Diminution of this quantity is followed by serious symptoms, which disappear when the amount is again increased. Inhalation of the vapor of ol. juniperi has been tried on another division, the effect in some cases being well marked, but negative in others. The bowels are kept open by occasional doses of Murchison's powder on one division, by elaterium on another. Iron and quinine are given as tonics; the tr. ferri chlorid. being preferred by some.

A favorite prescription on the second division is,—

℞ Ferri sulph. exsic., gr. ij;
Quin. sulph., gr. j;
Ext. gent., q. s. M.
S.—Pil. j t. i. d.

If there be much anasarca, strychniæ sulph. is sometimes added to the above. In ascites, stupes of digitalis infusion are placed over the kidneys occasionally with benefit.

If delirium or convulsions ensue, in addition to the use of eliminative remedies, as elaterium, hypodermic injections of Magendie's solution of morphia are given, with the object of lessening the sensibility of the nervous centres to the action of the blood-poison. This treatment, suggested by Prof. Loomis, seems to be efficient in a large proportion of cases. In uræmic coma, stimulating enemata, with the hot-air bath, are the means usually adopted.

DELIRIUM TREMENS.

In cases of injury complicated with this trouble, Dr. Griffith, of the third surgical division, is in the habit of giving as a drink, in twenty four hours, infus. artemisiæ absinth. Oij; also giving porter. On other divisions, chloral hydrate is given, associated with bromide of potassium, as in the following:

℞ Chloral-hydrat., ʒij;
Potass. bromid., ʒiv;
Aq. cinnamomi, ʒij. M.
S.—ʒj q. i. h. until sleep occurs.

Usually only a few doses are required to produce this result.

CHOLERA INFANTUM.

If the disease have reached the cold stage, the best results are obtained by the administration of the "eau albumineuse," prepared by dropping the white of an egg in a teacup half full of water, gently stirring (not beating), until the albumen is dissolved. To this brandy is added, so that each drachm contains from two to five drops, varying with the age of the child. A teaspoonful is given every half-hour, the patient being also wrapped in blankets, and the surface stimulated by applications of ol. camphorat.

W. H. FARRINGTON, M.D.

ST. MARY'S HOSPITAL—DISPENSARY FOR NERVOUS DISEASES.

SERVICE OF CHARLES K. MILLS, M.D.

Reported by JOHN S. BAGG, M.D.

SPINAL ANÆMIA.

J. R. W., æt. 25, had been for three years a sufferer from various nervous and visceral disturbances, and for about two years of that time he had been unable to attend to any regular work, owing to the condition of his health. From the patient's account of his symptoms, his disorder had been protean in character, and he had been treated at intervals by different physicians for dyspepsia, heart-disease, cerebral congestion, general debility, etc.

The patient complained of an inability to concentrate his thoughts upon any subject, and of an almost constant feeling of uneasiness in the head, which some-

times seemed constricted, at other times light; but he was very little annoyed with headaches. Disturbance of the stomach was a prominent feature in the case. He was troubled nearly all the time with gastric flatulence and acidity, and a feeling of oppression in the epigastric region, and occasionally with pain in the stomach, and nausea. He was never constipated, but now and then had attacks of diarrhœa, and suffered frequently from abdominal pain and soreness, which he attributed to wind. Palpitations and pain over and about the region of the heart, probably intercostal neuralgia, were among the occasional symptoms. During the greater part of the last two years he had been subject to nocturnal emissions twice and three times weekly. He had difficulty in walking, from a feeling of weakness in the legs and of uncertainty of gait. He always felt better when lying down, and just after arising from the recumbent position. He stated that his mind was always in an irritable condition.

On examination of the spine, tenderness on pressure was found from the third to the tenth dorsal vertebra, most marked over the eighth and ninth; and there was tenderness also over the third and fourth lumbar vertebræ. Slight pain in the cord, chiefly in the upper dorsal region, was developed by percussion. The case was diagnosed to be one of anæmia of the posterior columns of the spinal cord.

Blisters over the seats of tenderness were ordered to be applied and repeated as soon as possible. The following prescription was given:

℞ Strychniæ sulphat., gr. j;
Ferri pyrophosph.,
Quiniæ sulph., āā ʒss;
Acid. phosph. dilut.,
Syrupi zingiberis, āā fʒij.—M.

S.—A teaspoonful to be taken three times daily, immediately after each meal.

The induced current was applied twice weekly to the muscles of the body and extremity. Exercise in the open air, and good nutritious diet, were also enjoined.

At the time of making this report the patient has been three weeks under the treatment just given, the blisters having been twice repeated. The palpitations, neuralgic and other pains, flatulence, acidity, nausea, and nocturnal emissions have ceased to annoy him. He experiences very little uneasiness in the head, and can walk a long distance without difficulty. He expresses himself as feeling better than he has done before for nearly three years. The same treatment will be continued.

CASES OF OVARIOTOMY.

BY WASHINGTON L. ATLEE, M.D.,
Of Philadelphia.
Reported by J. Ewing Mears, M.D., of Philadelphia.

CASE 245.—*Unilocular ovarian tumor—Incision four inches in length—Inveterate adhesions—Death on the ninth day.*

November 8, 1871, Dr. Atlee visited, in consultation with Drs. Fay and Gemmill, Mrs. T. McC., an ignorant Irishwoman, living in a small shanty on the outskirts of Altoona, Pa. The patient could give no satisfactory account of her age; she appeared to be about forty years old. Menstruation commenced at the age of eighteen or nineteen, and has always been regular. She was married in 1868, and has had one child, now eighteen months old.

In 1866 the abdomen began to enlarge, the enlargement gradually increasing until Dr. Atlee saw the patient, when she was larger than a woman at full period of gestation. On examination, all the symptoms of a unilocular cyst were found to be present. The pelvis was free, the uterus was movable, and admitted the sound two and one-half inches.

Ovariotomy was performed, the following-named gentlemen being present: Drs. Gemmill, Fay, Findley, and Bell, of Altoona, Roller and Irwin of Hollidaysburg, Miller of Huntingdon, Clark of Bell's Mills, and Bloom of Martinsburg.

In this case, owing to the very extensive and firm adhesions which bound the cyst to the anterior wall of the abdomen, there was great difficulty in finding the line of demarcation. In some remarks appended to this report, Dr. Atlee directs attention to an unfailing test which he applies in these cases, and which prevents the occurrence of such an untoward accident as the extended separation of the parietal peritoneum.

The pedicle, which was not large, and was of good length, was secured in a three-quarter inch space of Dr. Atlee's clamp. The right ovary was examined and found healthy. The tumor was unilocular, involving the left ovary, and, with its contents, weighed twenty-five pounds.

During the four days succeeding the operation the condition of the patient was excellent, not an unpleasant symptom presenting itself; and this in spite of her wretched surroundings. During this time the pulse did not exceed ninety. Death occurred on the ninth day. Dr. Fay writes in reference to the case as follows: "For the first four days I thought she would recover; but such nursing I have never seen, and I hope never will see again. Septicæmia was, I think, the cause of her death."

Remarks by Dr. Atlee.—The above case illustrates one very important practical point in the operation of ovariotomy. It is this: *immediately after making the incision through the walls of the abdomen, the index finger should be passed up to the region of the umbilicus, and if it can be swept freely across from side to side it must be within the abdomen.* This, of course, is an easy matter when no adhesions exist. It is always possible in parietal adhesions, when the finger is inside of the peritoneum. It is not possible, without the most unwarrantable violence, when the finger is between the layers of the abdominal parietes. The non-observance of this rule has led to the separation of large portions of the peritoneal layer of the walls of the abdomen, even when no adhesions existed, the operator having mistaken the peritoneum itself for an adherent cyst-wall. When, however, parietal adhesions do exist, the mistake may be more excusable and more readily made, particularly in such a case as the one just related, where the peritoneum is thickened and more strongly incorporated with the cyst-wall than with the wall of the abdomen. The most convenient and infallible test of being within the abdomen is *the ability to freely move the finger to and fro past the umbilicus.*

TRANSLATIONS.

ON THE INFLUENCE OF ARTIFICIAL RESPIRATION IN STRYCHNIA-POISONING.

By Dr. Julius Rossbach. Translated from *Centralblatt für die Med. Wissenschaften*, May 31,

BY WM. ASHBRIDGE, M.D.

DR. ROSSBACH was induced to perform these experiments to ascertain the method in which strychnia acts upon animal organisms, by the fact that he was never able to confirm the statements of Leube in regard to the effect of artificial respiration in saving the lives of animals to whom poisonous doses of this drug had been given. The animals used for the experiments were rabbits, and the poison was administered hypodermically, by introducing it into the jugular

vein, and by the stomach. The results of the several experiments were as follows:

I. Hypodermic Injection of Strychnia.—0.001 strychniæ muriat. given to rabbits of the weight of 1000 to 1280 grammes did not excite convulsions nor increase the reflex irritability to any observable extent.

0.002 given to rabbits of 1180 to 1300 grammes' weight excited, after fifteen minutes, tetanic spasms; the animals, however, recovered without artificial respiration, which in fact seemed to have no influence upon the appearance of the convulsions or upon their duration or intensity.

0.00275 of the poison killed all rabbits from 1150 to 1310 grammes in weight, whether artificial respiration was employed or not.

0.003 was absolutely fatal for all animals ranging in weight from 1205 to 1419 grammes, whether artificial respiration was resorted to or not.

From these experiments, in which the poison was injected hypodermically, the conclusion would be drawn that neither the character nor intensity of the spasm was affected by artificial respiration, nor was it in a single instance able to save life, its only effect being to keep up the pulsations of the heart for an hour or two longer.

II. Introduction of Strychnia into the Jugular Vein.—0.0005 strychniæ muriat. injected into the jugular vein of rabbits weighing 1000 to 1290 grammes appeared almost without influence; no spasm was induced.

0.00075 strychniæ muriat. caused, at the end of five minutes, violent tetanic spasms whether artificial respiration was resorted to or not; but still it was not an absolutely fatal dose, since rabbits weighing 1170 to 1220 grammes survived it without artificial respiration, one of 1620 grammes lived with this aid, while a third, of 1350 grammes, died without it.

0.001 excited similar appearances to 0.003 given hypodermically, with the exception that even when the most intense apnœa had been previously induced, the convulsions followed almost instantly the introduction of the poison into the veins, but even after this dose many animals lived without artificial respiration.

0.00125 killed rabbits of 1400 to 1590 grammes almost immediately, whether artificial respiration was employed or not, even when intense apnœa had been previously caused.

III. Strychnia introduced in the Stomach.—0.001 strychniæ muriat. excited, in animals weighing 1200 grammes, but transient and slight manifestations.

0.002 killed animals of 1010 to 1350 grammes' weight, even when intense apnœa had been induced; artificial respiration was not able to save one life.

From this, the conclusion of Leube that the action of strychnia in the stomach is more intense than if given hypodermically, is confirmed.

Artificial respiration, however, has no influence either in maintaining the life of an animal poisoned with strychnia, or upon the intensity or duration of the convulsions. The movements, indeed, needed to produce inspiration often furnish the impulse for an outbreak of the spasms. The prolongation of life which it is possible to attain by artificial respiration must be understood to be but a duration of the heart's action for the space of a few hours; for the other signs of life, as, for example, irritability of the cornea, are always wanting, and the pulsations can only be noticed by the ear upon the breast of the animal.

The case is similar to the condition due to a section of the spinal cord high up: the animal is fatally injured, but the pulsations of the heart can be kept up by artificial respiration for some time, as a heart cut from the body under certain conditions can be kept pulsating.

The conclusion, then, is that as a means of saving life in strychnia-poisoning, in rabbits at least, artificial respiration is of no value.

SO-CALLED SEPARATION OF THE RETINA.

By R. Berlin. Translated from *Centralblatt für die Med. Wissenschaften*

BY WM. ASHBRIDGE, M.D.

In a short time Berlin had an opportunity of observing eight cases of injuries to the ball of the eye caused by blunt instruments, and in all these cases the prominent symptoms were the following:

1. Moderate diminution of the central intensity of vision, without any disproportionate involvement of the peripheral power of vision.
2. Rapid episclerotic injection.
3. Great resistance of the sphincter pupillæ to the action of atropia.
4. Characteristic, gyrated, whitish-gray cloudiness of the retina.

In regard to this last symptom, Berlin asserts that the diminution of the power of vision, as a rule, reaches its maximum only when the cloudiness of the retina has commenced its retrograde metamorphosis, and after the entire disappearance of this symptom it remains several days. The coming and going of the serous infiltration and cloudiness of the retina usually extends over seventy-two hours. About the same time was needed for the experiments made upon rabbits in which blows upon the cornea were made with a glass rod, for the appearance and disappearance of the same symptoms. If the blows are inflicted upon the sclerotic, analogous changes are found not only upon the adjacent parts of the retina, but also upon the part directly opposite. This last is accounted for by Berlin by the resistance of the walls of the orbit. The contraction of the retinal vessels following the injury was in no case followed by their enlargement. This fact, among others, is made use of by the observer to disprove the separation of the retina which is assumed to account for the diminution in the power of vision, and he supposes that this effect is due to the violence done to the trunk of the optic nerve.

The pathological conditions proved by Berlin in the eyes of the rabbits subjected to his experiments were: a serous infiltration, or cloudiness, plaiting of the retina, which could only be regarded as a secondary product due to a hemorrhage between the choroid and the sclerotic. Finally, it was observed that, without exception, in rabbits the cause of the cloudiness of the retina and the diminution of the power of vision were not proportional; and it is in the highest degree probable that this is also true for the human eye.

PARALYSIS OF THE LEFT LOWER EXTREMITY AND THE BLADDER, DUE TO A NEUROMA ON THE ROOTS OF THE FIRST TWO SACRAL NERVES OF THE LEFT SIDE.

Reported by Dr. Löwenfeld. Translated from *Wiener Med. Presse*

BY WM. ASHBRIDGE, M.D.

The patient, F. K., was admitted into the hospital September 11, 1872; was the wife of a mason; at the time of her admission into the hospital was 46 years of age, and gave the following history of her case:

Five weeks previously she had been attacked with moderate pains in the sacral region, which from time to time increased in severity and gradually extended down the left thigh; no cause could be assigned for their appearance. She was finally obliged to give up her household duties, since locomotion became so painful that she was compelled to remain in bed.

For some days previous to her admission she suffered also from dull pains and a feeling of tension in the lower part of the abdomen; her general condition in other respects was unaltered. In the year 1853, after her fourth confinement, she suffered from an attack of inflammation of the womb, which confined her to bed for three months, followed apparently by perfect recovery, and her menstruation had been normal and her health good up to this attack from which she was admitted. Upon admission, her pulse and temperature were normal; her body was small, but well nourished; the thoracic organs were healthy. At the lower part of the abdomen was a tumor the size of a child's head, due to the distended bladder, from which nineteen hundred cubic centimetres of strongly acid urine, dark-brown in color and containing uric acid salts and earthy phosphates, was drawn off. No abnormal prominence or point of tenderness could be found along the vertebral column, and whilst lying upon her back no pain was felt by the patient. She still had power of motion to a considerable degree, although attended with pain radiating from the sacrum to the thigh of the affected side, while passive motion could be made in all directions. The sensibility in the affected limb was but little disturbed: only on the front and outer side of the left thigh could be noticed any diminution of sensibility as compared with the right. The appetite was good; defecation was normally performed. The patient during the eleven days following her admission was daily catheterized, and while in a state of rest was quite comfortable; but on the 22d of the month an attack of febrile symptoms came on, the temperature rose, the pulse reached 120 beats in a minute, and on the 25th an eruption characteristic of a mild attack of varioloid showed itself. She was transferred to the smallpox wards, and on the 1st of October returned again, having passed through a light attack of varioloid. At this time her condition was much more unfavorable than upon admission. Over the sacrum there was a bed-sore of considerable size; she had lost flesh, and the loss of motion of the left leg was complete; even passive motion induced intense pain. From the crest of the ilium down to the lower third of the thigh, sensibility was completely lost; on both surfaces of the foot there was slight sensibility. The urine was of a dirty grayish-brown color, alkaline, cloudy; specific gravity 1025; contained the earthy phosphates in increased quantity, and also a considerable amount of mucus and shreds of mucous membrane. In the sediment were discovered epithelium from the bladder, numerous mucus-corpuscles, pus-corpuscles in less abundance, and crystals of the triple phosphates and of urate of ammonia. During the following nine days the patient became gradually worse, with moderate febrile symptoms, failing appetite, the evacuations from the bowels remaining normal. On the night of the 10th of October she had a chill of an hour's duration; the next morning the skin presented a slight icterode hue; the paralyzed limb had entirely lost its sensibility, and the bed-sore was much increased both in depth and in extent. Two more chills followed, the surface of the body and the conjunctiva became of a lemon color, and on the afternoon of the 12th the patient died. At the autopsy, an examination of the spinal cord revealed the following:

The spinal cord was anæmic, somewhat œdematous; the roots of the first two sacral nerves, even up to the intervertebral ganglia of the left side, were surrounded by a round mass of connective tissue of a grayish-red color and rather larger than a bean in size. These masses of connective tissue were intimately united with the dura mater, which at these points was thickened and pale, and under the microscope they showed the characteristics of fibrous sarcoma.

In this case the spinal cord, so far as its texture was concerned, remained entirely unaltered, and the symptoms, whether the tumors took their origin from the dura mater or from the roots of the first two sacral nerves, must be accounted for entirely by the compression and atrophy of the nerves themselves.

The Restorative Force of Nature in Delirium Tremens (by Ely Van de Warker, M.D.: *N. Y. Medical Journal*).—Dr. Van de Warker commences his article by stating that, although the literature upon this subject is extensive, the profession, so far as treatment is concerned, with the exception of blood-letting, stands where it did in the old days of the three-bottle men. The use of chloral he looks upon as but a new method of meeting old indications, and he feels confident that accidents will occur from its administration if used in this disease.

The doses of opiates given he regards as dangerous, and thinks that the state of the system in this disease should not be designated as a tolerance of narcotics so much as a resistance of their effects; and as a possible explanation of the fatal result sometimes met with even in uncomplicated cases of delirium tremens, he suggests the rapid depression of the vital powers following large doses of narcotics.

Insomnia he looks upon as but a symptom, and thinks that the theory that if sleep is induced the disease is cured is erroneous, inasmuch as the muscular tremors and the hallucinations, though modified in form, may continue after the patient has slept. He divides cases of delirium tremens roughly into two classes: the first including persons habitually temperate who have the disease as a result of sudden excess, and the second containing those who are victims of long-continued excess, which must result in serious changes of the nerve-centres. In the first class insomnia is the most marked symptom, sleep is usually readily induced, and a cure speedily follows. In the second class it is almost impossible to procure sleep in the early stages, the mania is most active, and the tremors are marked. In these cases the insomnia is but a symptom of a grave pathological condition, and narcotics are of but little effect until after two or three days the morbid condition amends and sleep is procured either spontaneously or by a comparatively mild dose of an opiate. His remarks are intended to apply with more directness to this last class of cases. Dr. Van de Warker has treated several uncomplicated cases simply with Epsom salts or pil. cath. comp., using no narcotics whatever, and the results observed have been favorable: he noticed particularly the rapid convalescence of the patient, there being no period of prostration following the attack, and but little impairment of the digestive function.

Alcohol from Iceland Moss.—We learn that alcohol is made in St. Petersburg and the northern provinces of Russia from Iceland moss, and that this branch of industry has become quite extensive. In Finland, Archangel, Pskow, and Novgorod, brandy and alcohol are manufactured from the mosses and lichens growing there. The manufacture of lichen and moss spirits began in Sweden, and from there went to Finland. At the last Russian Industrial Exhibition specimens of the alcohol were exhibited which were made in the distillery at Wincilas and from the Lewin manufactory in the city of Borgo, as well as from the factory of Zadler and of Count Trabirki in St. Petersburg. German, English, and French manufacturers were well pleased with its quality. In Northern Russia it is said that this branch of industry brings in a net profit of 100 per cent., and in the interior countries 40 to 100 per cent.—*Druggists' Circular.*

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 6, 1873.

EDITORIAL.

POPULARIZING SCIENCE.

ONE of the distinctive features of the present decade is the immense impetus which has been given to the popularization of science.

In our leading daily papers learned correspondents discourse of geology and the flora of the lands they visit; copious reports of the meetings of savants are served up with the spiciest of literary condiments; and even the weather has technical editorials written concerning it. A department of science in our first magazine, and at least one popular serial devoted entirely to it, mark also the setting of the current. Even art is deriving inspiration from the dry bones of anatomical science; and M. Griset, a French artist, has given us some capital sketches of the pre-historic glory of man. One of these water-colors, entitled "The Neanderthal Man," represents our illustrious forefather with a profile just sufficiently suggestive of that of the Neanderthal skull to be very amusing, and a figure which has doubtless been conceived from reading Huxley's "Man's Place in Nature." The diminutive thumb, the monkey-like grasp of the stone hatchet, the elongated heel, the hirsute skin, and the short, slender leg, scarcely hiding beneath the scrawny skin the platycnemic tibia, are all there in their pristine ugliness.

Shades of art and science! even this sketch has not escaped the rage of the spoiler. In one of our illustrated papers it has recently been popularized,—every distinctive feature omitted, every characteristic overlooked, the whole point of the matter rasped away. So it is always when any but men of real scientific taste and knowledge attempt to popularize. But, worse than all, out from this reproduction of Griset's really sparkling sketch stares at us the unmistakable modern Esquimaux dog!

Verily, Science, though she may be courted, has, like the woman of old, suffered many things from many physicians.

And now the theatrical folk must needs be on the top of the wave, and add a piquance to the classic "Tempest" by introducing the Neanderthal Man in the character of Caliban. Despoiled of all his ape-like features save his hairy skin, he has had given him the face of an Indian and the canine teeth of a boar, and has been made of such nature that we might, as was said by a Massachusetts Senator of a certain statue, all fall down and worship without sin; for surely this Caliban is like nothing in the heavens above, in the earth beneath, or in the waters under the earth. Moreover, this bizarre figure is in direct opposition to the spirit of the text, where Caliban is frequently spoken of as compounded of fish and man,—as Trinculo says, "being but half a fish and half a monster,"—and as having "a very ancient and fish-like smell." To hades with such scurvy monsters! May they

> "all be turned to barnacles, or to apes
> With foreheads villanous low."

MEDICAL FELLOWSHIPS.

AMONG the many truths told us by Mr. Tyndall during his recent visit to this country, none were more needed to be told than those referring to matters of education. He said we needed above all things a little more pure science. The pursuit of truth for its own sake, especially that form of it embodied in the inductive sciences, would be, in his opinion, a saving clause to the corrupt tendencies everywhere seen in our public affairs. How far the so-called science of medicine may be included in the stricture of Mr. Tyndall may be a subject concerning which there is doubtless a great variety of opinion; but we believe that there need be none upon at least one phase of the question, viz., that very many individuals of influence in the profession have no sympathy with abstract scientific truth. If they do not entertain an outspoken contempt for the medical scientist, they look upon him as a fanatic to be good-humoredly indulged. Paltry encouragement is given to the few who devote themselves to research,—meeting with indifference and receiving warning for their temerity, where they

have a right to expect approval. "Leave off Science," says Nestor, "or you will be as poor as poverty!" and, unfortunately, Nestor is right. Magendie has made us his confidant on this subject, and this is what he tells us: "I had at one time but five sous a day to live upon, and a dog to keep besides." And we recall the story of Leuret, who, while a soldier, sold his rations that he might buy candles and books, only to die of over-work and of insufficient food. We know all this; and yet in every age we will have our Magendies and our Leurets. Would it not be wiser for Nestor to stop lecturing the votary, and use his influence towards securing him a decent livelihood?

It reflects no credit upon the profession that while in other departments of science fellowships or endowed professorships support the student, there are none in medicine. Were the medical scientist to cultivate his speciality with the same tenacity of purpose that marks the careers of his collaborators in other departments, he might earn, perhaps, his five sous a day, and be thankful for so much.

It would not be a difficult matter to endow several first-class fellowships in connection with our medical schools, to encourage research, particularly in anatomy, physiology, and therapeutics. These would have great influence in raising the standard of teaching, improving our reputation as scientific observers abroad, and in every way resulting to the advantage of those concerned. Cannot something be done in this direction by bringing the subject before the notice of those gentlemen whose munificent endowments to our charitable institutions we are so often called upon to record, or by inviting the attention of the alumni of our different schools to its importance?

MR. ERICHSEN'S LATE ILLNESS.

IT will be recalled by our readers that we announced a few weeks ago the serious illness of Mr. Erichsen, caused by an injury sustained in performing a surgical operation. From a letter dated London, August 11, just received by one of his friends in this city, and from which we subjoin a few extracts, it will be seen that his health has been fully restored much sooner than had been anticipated by his professional advisers:

"I am thankful to say, and I am sure that you will be pleased to hear, that I have quite recovered from my recent severe and serious illness, and that I am feeling stronger and in better health than before its occurrence."

Mr. Erichsen's illness, which came so near proving fatal, arose from an operation-wound while overworked and tired out by the labors of a long winter. He frayed the skin of the *left* index finger in tying sharply with compressed whip-cord a portion of the stump of a tongue which he had just excised for epithelioma. This slight injury was followed by extensive and intense inflammation of the hand and of the lymphatics of the arm, followed by general blood-poisoning, with metastatic intra-pelvic abscess and deposits in the *right* hand and left shoulder.

We congratulate Mr. Erichsen upon his rapid recovery; and we are sure that every member of our profession will cordially unite with us in wishing him renewed health and increased prosperity.

WE have long thought that those architects who make a speciality of ventilation have a hard lot of it. What with the inherent difficulties of the subject, the stupidity of some owners, and the confident half-knowledge of others, their trials must be many. According to the *British Medical Journal*, a new difficulty has arisen in the London courts in the persons of the high dignitaries the judges themselves, although it is stated that it would be difficult to suggest anything more ingenious and complete than the modes of ventilation practised at the Westminster courts, or to devise a more intelligent and careful surveillance.

"The problem, of course, is to change the contained air sufficiently to prevent it from becoming loaded with the products of respiration. It is possible to ventilate adequately the smallest space into which a man can be crammed, by producing sufficiently rapid currents of air; and means are at hand, in some of the courts, for blowing the judges and jury out of their seats, and carrying the wigs and papers of the barristers floating over St. James's Park. But the toleration of currents of air, or draughts, as they are called, is very limited, both with individuals and with bodies of men. Hence it is found necessary, whenever it is desired adequately to ventilate any building permanently occupied, to allow sufficient floor-space, and apertures of ingress and egress of such size as will give about twelve hundred feet of cubic air for each individual, and will afford facilities for producing a movement of air just sufficient to produce a total change of air about twice an hour. In the courts of law, however, witnesses, jurymen, and public are packed like herrings in a barrel; and to produce anything like the change of atmosphere necessary to afford a pure, cool and respirable air, a whirlwind must be blown through the court. The conditions to be satisfied at present are, in short, impossible. The difficulty is in some cases aggravated by the extreme susceptibility of some venerable members of the bench to anything like perceptible movement in the air. We have seen repeated written orders from Lord Chief

Justice Cockburn to close air-holes, close windows, and shut ventilators; and the rule of the judges is absolute in such matters. The bar and the public must endure the excess of discomfort as well as they can. But even where such susceptibilities do not exist, the present courts are so ill adapted to receive the crowds who are often packed tightly into them—not always the most dry, savory, and well-washed crowds—that it is impossible to ventilate them adequately without driving through them, while the courts are sitting, the four winds of heaven; and this is not to be thought of."

IN our miscellaneous column will be found an editorial written by that venerable apostle of gymnastics and physical culture, Dr. Dio Lewis, which, although decidedly and amusingly shrieking in its tone, has some force and truth in it. In acknowledging this, it ought, however, to be distinctly stated that the picture of the suffering caused by vivisection is excessively overdrawn, and the asserted frequency of its practice exaggerated. The number of the profession who have ever practised vivisection is in reality very small. We do think, however, that the practice of it by students of medicine, except under competent direction, should be discouraged by the professors. The best remedy for its abuse would be the affording of the necessary direction; and hence, as a means of humanity, we hope all our colleges will soon have attached to them physiological laboratories, where the young working-power now lost may be turned to good account.

After all, it is supremely comical to see a public opinion which allows the life of the horse to be slowly dragged out by the ceaseless toil of the street-car or crushed by the spur and goad of the race-course,—which applauds as sport the cruel daily maiming of thousands of birds,—it is comical, we repeat, to see such a public opinion raving against vivisection. The pain inflicted by vivisection is to the pain inflicted by sportsmen as an ant-hill is to the pyramid of Cheops.

IN a somewhat recent number of the *Bulletin Général de Thérapeutique*, M. Dannecy proposes the use of bread made from roasted flour for diabetic patients, instead of gluten biscuit. He asserts that roasted starch cannot be converted into glucose, and that bread made out of the various farinas so torrefied is greedily eaten by patients who have been restricted to the ordinary preparation of gluten until they have become thoroughly disgusted. Moreover, under its use the thirst lessens, and the digestive derangements are markedly ameliorated. The good effect upon the elimination of sugar by the kidneys is at least equal to that obtained by the exclusive use of the classical diabetic diet.

LEADING ARTICLES.

REMARKS ON THE NEW CHEMICAL NOMENCLATURE.

BY W. H. H. GITHENS, M.D.

(Concluded from page 764.)

UNDER the old system of nomenclature, the chemical compounds which were called salts were divided into two groups,—halogen salts and amphigen salts: the former were so called from sea-salt,—sodium chloride,—which was the type. The latter group were supposed to be formed by the union of two binary compounds: thus, potassium sulphate was considered to be a compound of sulphuric acid and potassium oxide. As it is impossible to prove such a theory, it is obviously better to adopt a simpler one, especially as the latter is capable of greater generalization. The new theory gives all of the oxygen to the acid, which then unites directly with the elemental base. Again, absolute acids, like SO_3 and N_2O_5, are known to exert no acid properties unless water be present. Thus the acid becomes possessed of an additional equivalent of oxygen, while the hydrogen acts as a base which is replaced by another element when a salt is formed. Thus, the exact composition of sulphuric acid would be SO_4H_2, of potassium sulphate $HKSO_4$, of sodium sulphate Na_2SO_4, of nitric acid $H_2N_2O_6$ (sometimes written HNO_3), etc.

The anhydrous compounds formerly called acids are now called oxides or anhydrides. The reason for giving the latter name is found in the fact that they may be formed from acids by the abstraction of water. Thus, SO_3 is sulphuric oxide or anhydride, PO_5 is phosphoric oxide or anhydride. In some cases this change gives old names to other bodies, as in the case of the compounds of hydrogen with oxygen.

$N_2'O''$ is now called hyponitrous oxide, formerly nitrous oxide.

$N_2'''O_2''$ is now called nitrogen dioxide, formerly nitric oxide.

$N_2'''O_3''$ is now called nitrous oxide or anhydride, formerly nitrous acid.

$N_2^{v}O_4''$ is now called nitrogen tetroxide, formerly hyponitric acid.

$N_2^{v}O_5''$ is now called nitric oxide or anhydride, formerly nitric acid.

$N_2'''O_4''H_2'$ is the present formula for nitrous acid.
$N_2^vO_6''H_2'$ is the present formula for nitric acid.

The earliest record that I have been able to discover of these ideas is in the writings of Laurent and Gerhard. These gentlemen, with great labor, went over the entire ground, but did not live to reap their reward in beholding its universal acceptance.

Compounds are classed as binary and ternary. Binary compounds are those whose atoms are directly united: they are formed of two substances only. In naming these compounds, the positive or basic constituent is first given, and then the name of the negative, the termination of which is changed to *ide:* thus, sodium chloride.

If the positive element unites with the negative with more than one equivalence, it is indicated by changing the termination of the positive to *ous* or *ic:* thus,

$Hg_2'O''$, univalent mercury and oxygen, form mercur*ous* oxide.

$Hg''O''$, bivalent mercury and oxygen, form mercur*ic* oxide.

Ternary compounds are those whose dissimilar atoms are united by the aid of some third element. Of the bodies thus formed, by far the larger proportion are compounds of oxygen. These bodies may be divided into acids, bases, and salts.

An acid consists of one or more negative atoms united by oxygen to hydrogen, as $\bar{S}—O_4—H_2$, sulphuric acid.

A base consists of one or more positive atoms united by oxygen to hydrogen, as $\overset{+}{K}—O—H$, potassium oxide.

A salt contains a positive atom or group of atoms united by oxygen to a negative atom or group of atoms: thus, $H\overset{+}{K}—O_4—\bar{S}$, potassium sulphate, $\overset{+}{Na_2}—O_6—\bar{N_2}$, sodium nitrate.

The terminations *ate* and *ite* and the prefixes *per* and *hypo* have the same value and uses as formerly.

Acids are divided into *ortho-* and *meta*-acids. Ortho-acids are those in which there are the same number of atoms of oxygen and hydrogen. Meta-acids contain an excess of oxygen. They are formed by taking water from the ortho-acids.

$S^{vi}O_6''H_6'$ is ortho-sulphuric acid.

$S^{vi}O_6''H_6'$ less $H_2O = SO_5H_4$, which is mona-meta-sulphuric acid.

$S^{vi}O_6''H_6'$ less $2(H_2O) = SO_4H_2$, which is di-meta-sulphuric acid.

The hydrogen in an acid is called basic hydrogen: it may be displaced by a more strongly positive atom or group of atoms.

Acids are called mono-basic, bi-basic, tri-basic, etc., according as they contain one, two, three, or more atoms of basic hydrogen. In ortho-acids the basicity is equal to the quantivalence of the negative atom.

The terms ortho and meta are also applied to bases with the same meanings. The hydrogen in a base is called acid hydrogen, and is displaceable by a more strongly negative atom or group of atoms. The positive or negative condition of hydrogen is only a relative one. If a compound containing hydrogen be decomposed by electricity, the other member of the compound will take its proper position at the positive or negative pole, and the hydrogen will in either case go to the other: so in compounds it acts either an acid or a basic part.

Ternary bodies are also formed with nitrogen as the linking element, and, as in the case of the oxygen compounds, these bodies are divided into three classes, which in this case are called *amides, amines,* and *alkalamides.*

An amide contains one or more negative atoms united by nitrogen to hydrogen: $\bar{I}_2—N—H$ is diniodamide.

An amine contains one or more positive atoms united by nitrogen to hydrogen: $\overset{+}{K}—N—H_2$ is potassamine.

An alkalamide contains both positive and negative atoms united by nitrogen: $\overset{+}{K}H—N—\bar{Cl}$ is chloro-potassamide.

An ammonia molecule consists of three hydrogen atoms united by nitrogen: thus, By exchanging a portion of the hydrogen for one or more positive atoms, an amine is produced; if for negative atoms, an amide, and if for both positive and negative, an alkalamide: they are, therefore, said to belong to the ammonia type.

To those who wish to look more closely into the subjects of which we have written, we take pleasure in recommending Barker's Elementary Chemistry: it is thorough, concise, and lucid.

REVIEWS AND BOOK NOTICES.

SIX MONTHS UNDER THE RED CROSS, WITH THE FRENCH ARMY. By GEORGE HALSTEAD BOYLAND, M.D., Ex-Chirurgien de l'Armée Française. Cincinnati, Robert Clarke & Co., 1873.

Perhaps we cannot give our readers a better idea of this interesting little book of nearly two hundred and fifty pages than by transcribing its brief preface. The doctor says,—

"During the siege of Metz, I found many leisure moments, and improved them by taking notes upon passing events, and writing an account of my personal experiences and adventures as Assistant Surgeon-Major in the 'Army of the Rhine.' They were made upon bits of paper; on my shirt-cuffs; in the lining of my képi, etc.: at times on the field of battle; at others while sitting on the floor of the barrack hospital, or reclining in my tent. They are composed without any pretension to literary merit, and are a simple statement of the facts told in my own language: as such I have the honor to place them before the public."

The doctor, we may say, has made good use of his shirt-cuffs: by the way, do they use paper cuffs in France? The book is written in a clear, straightforward manner,—written as though its author knew he had something to say, and simply said it. It is a popular work, containing nothing—so far as we have seen, and we have read most of it—technical, and has simply the interest of a narrative of adventures among most stirring scenes. We think that either in whole or in part it would form an excellent tract for the "Peace Society," showing as it does in a most forcible manner the unspeakable horrors of that hellish incarnation of human passions,—war.

THE CEREBRAL CONVOLUTIONS OF MAN REPRESENTED ACCORDING TO ORIGINAL OBSERVATIONS, ESPECIALLY UPON THEIR DEVELOPMENT IN THE FŒTUS. By ALEXANDER ECKER, Professor of Anatomy and Comparative Anatomy in the University of Freiburg, Baden. Translated by ROBERT S. EDES, M.D. New York, D. Appleton & Co., 1873.

This excellent little memoir is an attempt to lay an anatomical foundation for an accurate physiological and pathological knowledge of the human cerebrum, or, in other words, of an organology of the brain. It is, as it were, a minute topographical survey of the surface in which and under which lie the wonderful thinking and acting powers. From the very nature of the subject, it can have but little interest to the general mass of practitioners,—to any of whom, however, desirous of cultivating his memory we can commend it. To the profound student of cerebral life and disease we think the book will be most welcome. We have not as yet compared it with the cadaver; but, so far as we can judge without this, the work is as accurate as it is minute and thorough in its teachings. It certainly has cost its author a great deal of labor, and as the original has been appreciated abroad we trust the reprint will be here.

Dr. Edes has done his part well, the sentences being free from that German construction so often seen in translations,—arrangements of words which, whilst they may coincide with the Teuton's idea of verbal elegance, are as much out of place in English as the Englishman's "stove-pipe hat" and tight broadcloth dress-suit are out of place in the tropics.

GLEANINGS FROM OUR EXCHANGES.

THE VALUE OF SODIC BROMIDE AS A NERVOUS SEDATIVE (W. Ainslee Hollis, M.D.: *The Practitioner*, August, 1873).—Bromide of sodium, although known to have a therapeutic action analogous to that of the bromide of potassium, has lately somewhat fallen into disuse, while the latter salt has been recommended as a remedy for nearly every disease. The bromide of sodium has a pungent saline taste, is freely soluble in water, and forms a colorless solution. Shortly after it is taken into the stomach, a burning sensation is experienced at the epigastrium; this quickly passes off, giving place to drowsiness and sleep, followed by numbness in the extremities, which does not disappear until several hours after waking.

The following cases illustrate its beneficial action in nervous diseases. Fred. B., æt. 21 years, came under treatment for epilepsy, November 13, 1872. From early childhood the attacks had occurred three or four times weekly. He was treated for the first month with thirty-grain doses of bromide of potassium thrice daily, combined with one-third of a grain of extract of belladonna at night. As the attacks diminished but little in frequency, a seton was inserted in the back of his neck; for a short time after this the fits appeared to be less frequent and severe, but, as he complained of lowness of spirits and debility, one grain each of sulphate of iron and sulphate of zinc were ordered to be taken three times daily. This was continued only one week, as the symptoms returned with their former severity. Bromide of potassium was resumed, in forty-grain doses: this, with the addition of succus conii and a fresh seton, composed the treatment up to May 22, 1873, no effect being produced. On the 22d he was ordered three grains of bromide of sodium three times a day; and during the next week he had only two fits. On May 29 each dose was increased to fifteen grains, and on June 5 to twenty grains: in the interval he had several attacks of "petit mal," but no marked epileptic seizures. After this he improved much in general health, and had but one fit. In another case, a boy 14 years old, who had been subject to epilepsy from birth, after subduing the paroxysms by taking ten grains of bromide of potassium three times daily, suffered no return on the substitution of three-grain doses of the bromide of sodium, although he felt much depressed.

In a third case of epilepsy, the fits were checked by taking daily fifteen grains of the salt in three doses; here also general depression was marked. This depression of spirits very frequently accompanies the use of the medicine in a watery solution, and might possibly be counteracted by the administration of a tonic in combination.

In two cases of nervous excitement due to mental anxiety, and in one of epileptic vertigo, small doses of the bromide produced great relief, while in a case of insomnia in an old man it appeared to do harm. We have, therefore, in sodic bromide, where judiciously used, a valuable nervous sedative.

MIGRAINE FROM INJURY TO THE HEAD (*The Practitioner*, August, 1873).—Dr. Douglas Morton offers the following observations, derived from personal experience, in support of the theory of the "neurotic origin" of migraine. His first attack he attributes directly to an injury received on his head in a fall. At the time of the accident he felt no pain, but rather a sensation of being stunned; shortly afterwards his vision became affected so that on directing his attention to an object he could see only the left half of it. Closing first one eye and then the other, he found that the injury to his eyes consisted in destruction of vision in the right halves of both, for with either closed he could see the left halves of objects looked at with the other. He was also unable to select suitable words to express himself, or to pronounce more than one letter at a time, although still able to intelligently follow a conversation. Headache soon set in, and increased rapidly in severity, being associated with nausea and vomiting, on the occurrence of which the disturbance of sight disappeared. The vomiting soon ceased, but the headache remained for some time. After an interval of seven years a second attack occurred: in this symptoms were noticed which had been overlooked in the first, viz., the appearance of a figure, trembling in space, apparently suspended a few feet before the eyes, and a sensation of numbness in the right cheek and the right side of the

tongue, which came on with the headache and after the optical phenomena had disappeared. In each of his subsequent attacks the symptoms were repeated almost exactly.

Dr. Morton remarks that he has been unable in every instance to connect an attack with any deviation from his usual mode of life, and that, while frequently suffering with headache due to digestive disturbance, his *sick* headache was distinct in the peculiar grouping of its symptoms and in the obscurity of its etiology.

A cup of strong tea or a glass of sherry wine taken at the outset of the affection has produced relief. The best remedy, however, in the author's experience, is guarana: several cases have been reported in which great benefit was derived from this drug.

Slight Poisoning from the Medicinal Use of Phosphorus (Dr. Anstie: *The Practitioner*, August, 1873).—While it has been proved that there are many patients who will bear much larger doses of phosphorus than those generally used, the following case shows that instances may be met with in which there is a greater susceptibility than usual to the poisonous influences of the drug.

A gentleman, aged 33, first applied for treatment in May, 1872. He had been subject from boyhood to periodical attacks of migraine, always preceded by vertigo and attended with vomiting; the latter occurring while fasting, and consisting of an acid liquid. In December, 1871, though he had a marked attack of sick headache, there was no vomiting, and the disease became more like ordinary neuralgia. The remedies which had so far been employed were quinine and iron, with strychnia and arsenic, the latter doing most good. The treatment adopted in May, 1872, was a course of arsenic and cod-liver oil, with an increased quantity of food; he was also advised to confine himself less strictly to business. When seen again, one year afterwards, he had improved in general health, but, as the neuralgic tendency still remained, he was directed to take, instead of the above prescription, a pill containing gr. $\frac{1}{30}$ of phosphorus three times daily. These he took from the 5th to the 12th of May, but during the last two days suffered from a constant and increasing burning sensation at the epigastrium; his urine became dark, and was found on examination to contain both albumen and blood, but no casts. The nervous symptoms had increased, the pain being less neuralgic and more continuous than before, with exacerbations each morning and evening, whereas formerly there had been only monthly paroxysms of pain. On May 14, after two days' rest from phosphorus, the renal and gastric symptoms having disappeared, he took, an hour before the morning exacerbation of pain was expected, five grains of quinine, and, singularly enough, never had any return of pain. From this time he steadily improved, though medical treatment was not resumed.

It might be supposed that the single dose of quinine produced the cure: he had, however, been previously saturated with it without benefit, and unless some powerful impression had been made upon the nervous system by the phosphorus, it is not probable that the quinine would have done any good.

The burning pain in the stomach, with the temporary hæmaturia relieved as soon as the medicine was discontinued, would seem to show that there was phosphorus-poisoning in this case. Thus it is possible that a patient may suffer slight degrees of phosphorus-poisoning from less than three-quarters of a grain in minute doses distributed over seven days. Such cases must, however, be quite exceptional.

A New Remedy for Dysentery (*Canada Lancet:* by William Kerr, Surgeon).—Twelve years ago an accidental circumstance led Mr. Kerr to attempt an improvent in the treatment of dysentery. Commencing with camphor and henbane added to opium, he came to the conclusion that the most efficient combination was one of opium, henbane, hemlock, stramonium, and digitalis. Although this as a rule was satisfactory, still failures sometimes occurred; and, concluding that some plants not found in the officinal list might possess efficacious properties, he began a series of experiments with some of the plants indigenous to Canada, not found in the Pharmacopœia. Sium lineare supplied the place of hemlock, this latter being found sometimes to cause pain in the bowels, while the former gave relief, and dulcamara supplanted henbane, being found to act more beneficially in the combination. The combination finally employed contained the following ingredients: opium, stramonium, dulcamara, digitalis, Sium lineare, Cicuta maculata, and Conio-selinum Canadense, the first four being officinal, the remainder non-officinal. All these are more or less narcotic, while some possess diuretic properties.

The combination without opium is slightly aperient, improves the appetite, promotes sleep, and tends to heal ulcerations of the mucous membranes. The office of the opium in dysentery is only to check the frequent motions of the bowels, the curative power being due to the other ingredients. In infants, and with some adults, digitalis does not act favorably, and in its place squills is substituted. Of either digitalis or squills but half a part is used; the other constituents are used in the proportion of a full part; the portion of the plant used is the leaf, excepting of course the opium and squill. The dose for an adult is six and one-half grains. This formula has been accepted after a series of trials extending over five or six years, more than thirty plants having been experimented with. The combination has been in use for seven years, and the concurrent testimony of several physicians as to its efficacy is brought forward. It has been employed not only in Canada, but also in other latitudes, in the Southern States, on the west coast of Africa, etc., and there is a remarkable uniformity in the testimony of all who have employed it. The combination has also been used with advantage in chronic dysentery and cholera infantum, and in some cases of summer cholera. The relief given is usually marked after the first few doses, and a cure in most cases of dysentery was attained in a week. From its success in so many severe cases of dysentery, summer cholera, etc., Mr. Kerr suggests the applicability of the combination to that still more terrible disease, Asiatic cholera.

MISCELLANY.

Vivisection.—Of all the chapters in the history of my profession, no other makes one breathe quick, and the cold sweat start, like that of vivisection. Perhaps my younger readers may not know what vivisection means. The dissection of an animal while alive for the purpose of making physiological investigations. With cutting, and burning with fire and acids, with starvation and thirst, it is possible to make the sufferings of a dog, for example, during his week or month in the physiologist's laboratory, something which the imagination would find it difficult to grasp. Then consider the number of dogs, and other animals, which physiologists have tortured to death under pretence of scientific investigations. That eminent physiologist, but indecent savage, Spallanzani, lived for many years in the midst of a hell of cries, yells, groans, shrieks, and

moans, proceeding from thousands upon thousands of animals undergoing his experiments. I ask my medical brethren what advantage to science came of it all? I have been a student of physiological researches and discoveries, and I affirm that of the myriads of helpless creatures that have been tortured in this way, not one in a million has made the least contribution to science. A great intellectual genius, like one of the Bells, or, perhaps, Brown-Séquard, reports an experiment upon some animal, with his deductions. Forthwith an army of brainless imitators get their dogs and begin. Of course there is not the least probability of any good coming of it all, but it has a scientific appearance. The poor helpless creatures meantime, all day and all night, suffer on, while the would-be physiologist makes notes, which in due time he will inflict upon some medical society, and, though nobody will get a single valuable suggestion, a few of the more brainless of the members will fancy that Dr. —— is, somehow, a scientific investigator, while the investigator himself rests his weighty head on his hand and sighs to think that he is one of the great physiological explorers. Hundreds of thousands of medical men have practised vivisection. Not half a score of them have contributed an idea to physiology. The boys in Harvard Medical College get the fever of vivisection every winter. They read in the journals that some German physiologist has tried this or that experiment upon a rabbit or a dog, perhaps an experiment which makes one's heart stop to read about, and these youngsters set about starting their inquisition. About two months ago, one of the young men from Harvard told me of some experiments the vivisectionists of the class had been making; and I honestly declare that I cannot recall that description without a shudder, even at this distance. I trust they will try next winter the law against cruelty on those Harvard vivisectionists.

Go and ask the eminent physiologists among the professors in Harvard, and they will tell you exactly what I tell you of the usefulness of vivisection.

Among the Romans, a gladiatorial show in which some horrible thing did not occur was regarded as a tame fizzle. The savage is ecstatic only when the tortures of his hapless victim are fiendish. Down in the animal nature of many a civilizer there is not a little of this passion for the horrible. It is this which gives zest to vivisections.—*To-Day.*

Freckles.—For the benefit of young persons afflicted with freckles, we would inform them that powdered nitre, moistened with water, applied to the face night and morning, will soon remove all traces of them.—*Druggists' Circular.*

Women Students at Zurich.—The Russian decree relative to women students at Zurich has produced great excitement in that town. All the newspapers are unanimous in condemning the arbitrary conduct of the Russian government in the matter, though several of them admit that the Russian women students often behave in a manner discreditable to their sex. One of the professors of the university of the town observes, in a letter to the *New Zurich Gazette*, that the expulsion of the Russian women from the university will probably be followed by a large increase in the number of the women students from other countries, as German, French, and English women have hitherto been deterred from going to Zurich for their education by the improper behavior of the Russian women who attend the lectures there. A correspondent of the *Cologne Gazette* asserts that upwards of one-half of the Russian women students at Zurich live disreputably, and that many of the Swiss families in the town have consequently refused to receive them in their houses. That some belong to secret political societies is also a matter of notoriety: one of them even acted as vice-president at a "red" meeting of working-men. The Russian women students have now decided, after some stormy meetings, that all but two shall leave Zurich next term, and proceed for the completion of their studies to Paris, Leipsic, Munich, and Heidelberg.—*Medical Press and Circular.*

Emotional Insanity.—At a recent meeting of the New York Medico-Legal Society, David Dudley Field, Esq., in discoursing upon "Emotional Insanity," concluded as follows:

"Children under the age of discretion, idiots, and imbeciles are not within the discipline of criminal law.

"The mental unsoundness of other persons, commonly designated as insanity or mania, is in itself, or is attended by, disease of the brain, so that no heat of mere passion, and no degree of mere frenzy, can in any just sense be pronounced insanity by either of the professions.

"That neither perceptional nor emotional insanity by itself, nor both together, can be accepted as excuse for criminal responsibility.

"That intellectual or volitional insanity absolves from criminal responsibility when, and only when, the reason has lost either the power of choice or the power of controlling the will.

"That in every case of acquittal on the ground of insanity the defendant should be forthwith placed in a lunatic asylum, and there kept until it is proved that he is restored to such a state of sanity as to remove all apprehension of a recurrence of the disease.

"That the present gradation of punishments is unsuited to the present condition of medical learning, and a change is required which shall make the law punish not only according to the harmfulness of the outward act, but according to the quality of the inward spring of action."

Gordenio.—William Gordenio was the first person upon whom the degree of Doctor of Medicine was bestowed. He received it from the college at Osti in 1320. —*Canada Medical Record.*

Keokuk boys exhibit their courage by buying half-ripe watermelons and eating them in the shade of bulletin-boards posted over with cholera-medicine advertisements.

EXERCISES ON ANÆSTHESIA.—We find in the *Buffalo Medical Journal* the following curious programme of a public lecture on Anæsthesia, lately delivered in New York:

"*Order of Exercises.*—Organ Voluntary. History of Anæsthesia, Dr. J. Marion Sims. Chemistry of Anæsthetics, Prof. R. Ogden Doremus, M.D., with Experiments. Practical Application of Anæsthetics in Surgery, Professor Frank H. Hamilton, M.D. Address by Rev. Henry Ward Beecher. Organist, Mr. Walter. Mayor Havemeyer will preside. For this occasion Mr. William Steinway has kindly tendered the use of Steinway Hall, Wednesday evening, May 21, 1873, at 8 o'clock."

It is a curious illustration of the difference of "the point of view," that this display was promoted by a number of the most eminent physicians and citizens of New York, and evidently suggests to their mind nothing which savors of the ludicrous or unseemly. No one would be bold enough on this side of the water to attempt what appears to us as incongruous a series of "exercises" as were ever presented on the boards of a theatre.—*British Medical Journal*, July 19, 1873.

"MRS. WINSLOW'S" SOOTHING SYRUP.—In the City Registrar's report of Providence, Rhode Island, for July, Dr. Snow says:

"There were two deaths in July from poisoning: one was from an overdose of morphine; the other from Mrs. Winslow's Soothing Syrup. There ought to be some power to stop the sale of a rank poison like Mrs. Winslow's Soothing Syrup under the false pretence that it is perfectly safe."

WE are glad to hear that the young lady upon whom Dr. Robert Battey, of Rome, Georgia, performed the extraordinary operation called normal ovariotomy, a year ago, has not only survived, but is in most excellent health. Her former pains have entirely ceased. Curiously enough, she had a flow from the womb, resembling the menstrual flux, every two to four weeks, up to a few weeks ago, since when she has seen nothing of it. —*Boston Medical and Surgical Journal.*

THE *Univers* announces with great joy that Mr. Darwin was rejected by 26 against 6 votes as corresponding member of the French Academy of Science. The six votes were given to him by the "friends of the Apes."

HOSPITAL APPOINTMENT.—Dr. J. Ewing Mears has been appointed surgeon to the St. Mary's Hospital, vice Dr. A. D. Hall, resigned.

DR. WILLIAM PEPPER has removed to 1811 Spruce Street.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM AUGUST 19, 1873, TO SEPTEMBER 1, 1873, INCLUSIVE.

WRIGHT, J. P., SURGEON.—Granted leave of absence for thirty days. S. O. 178, Department of Dakota, August 13, 1873.

BROWN, HARVEY E., ASSISTANT-SURGEON.—To proceed to Key West, Florida, and report to the commanding officer, Department of the Gulf, for assignment to duty. S. O. 170, A. G. O., August 22, 1873.

KINSMAN, J. H., ASSISTANT-SURGEON.—Granted leave of absence for sixty days. S. O. 67, Military Division of the Missouri, August 11 1873.

MAGRUDER, D. L., SURGEON.—Leave of absence extended thirty days. S. O. 171, A. G. O., August 23, 1873.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Leave of absence further extended thirty days. S. O. 173, A. G. O., August 27, 1873.

NOTSON, WILLIAM M., ASSISTANT-SURGEON.—Assigned to duty at Fort Gratiot, Michigan. S. O. 106, Department of the Lakes, August 26, 1873.

CARVALLO, CARLOS, ASSISTANT-SURGEON.—Assigned to duty at Fort Mackinac, Michigan. S. O. 106, c. s., Department of the Lakes.

KING, W. H., ASSISTANT-SURGEON.—Assigned to duty at Newberry, South Carolina. S. O. 151, Department of the South, August 26, 1873.

RETURN OF DEATHS AND INTERMENTS IN PHILADELPHIA FROM JULY 27 TO AUGUST 30, 1873.

ORIGINAL LECTURES.

A LECTURE
ON CHRONIC CERVICAL METRITIS.

USE OF THE ACTUAL CAUTERY.

BY F. H. GETCHELL, M.D.,

Clinical Lecturer on the Diseases of Women and Children in the Jefferson Medical College.

AMONG the most obstinate cases met with by the gynæcologist are those of chronic inflammation of the parenchyma of the neck of the uterus. This condition occurs oftenest among women who have given birth to children, and parturition and abortion are no doubt the most frequent causes. The disease may exist for some time without giving rise to much pain or uneasiness, but in cases of long standing the discomfort is generally very great. You will find the patient will complain of constant pain in the lumbo-sacral region of a dull, aching character, accompanied by a dragging sensation in the loins, and in many cases by a sharp pain in the region of the left ovary. The increased weight of the uterus always causes more or less prolapsus, and these patients will often tell you that they feel as though "every thing inside them was falling away." The prominent sympathetic symptoms are indigestion and all its accompanying annoyances, such as loss of appetite, nausea, constipation, and flatulence, often causing a semi-tympanitic condition of the abdomen that vexes the patient exceedingly. You will find it a very common thing for these patients to complain that they have not a dress they can wear, on account of the puffing up that is sure to come on a short time after eating. Headache is a very constant symptom; and, while the cephalalgia may exist in any part of the head, it is said by some authors to be located so generally at the top that pain at the summit of the head is by them considered pathognomonic of inflammatory disease of the cervix uteri. I have not found this to be the case; but, while I have found headache to be a very constant symptom of cervical metritis, in a majority of the cases it has been located in the frontal region, and not at the top of the head. You will find that most of these patients are very despondent and low-spirited, and in cases of long standing, particularly if they have been under treatment for some time without benefit, you will often find it very difficult to convince them that there is any hope of improvement. It is a remarkable fact that the mental depression experienced by the patient is often in striking contrast with her general appearance. It is no uncommon thing to see one of these patients presenting the appearance of perfect health, and to learn from her that life is a positive burden, and nothing depresses her more than want of sympathy on the part of her friends, accompanied with insinuations that her troubles are imaginary. This fact should always be borne in mind; and because the patient is fleshy, and to all appearance healthy, you must not decide that she complains without cause, till you have made a thorough investigation of the case.

The diagnosis of chronic cervical metritis is not attended with difficulty, and it is chiefly by the touch that you will ascertain whether the case is one of chronic inflammation of the uterine neck. You have no use for the speculum until you have made a thorough digital examination: the speculum is a therapeutic instrument, and is not to be compared with the educated finger as an aid to the diagnosis of uterine diseases. On introducing the finger within the vagina, you will find the uterus low down in the pelvic cavity, the cervix very much enlarged, in some cases to the size of a woman's fist. On pressing the finger firmly against the neck of the uterus, you will find it to be very hard; so firmly condensed is the tissue that all the elasticity of the healthy organ has gone, and we have hypertrophy and induration of the entire cervix instead. The os is generally patulous, and will often admit the end of the finger; but this is not always the case, for you will sometimes find the cervix enormously hypertrophied and the os will barely admit the uterine sound. By bi-manual palpation and the measurement of the cavity with the sound you will be able to diagnose the case from one of general metritis; and you will not confound a case of chronic cervical metritis with one of simple congestion if you remember that in the one case we have the cervical parenchyma injected with blood and communicating a soft elastic cushiony feel, softer than in the normal condition of the uterus, while if the enlargement be due to chronic inflammation we have an increased growth of the connective tissue, which exists in much larger quantity in the cervix than in the body of the uterus, together with an effusion of plastic lymph, which renders the cervix so dense and firm that you will at once recognize the existing condition as one of hypertrophy and induration.

In many cases the epithelium is gone in spots or patches, and there is hypertrophy of the villi. A variety of names are given to this condition of things, but the only point that I wish you to remember in this connection is that these ulcers, if we may call them such, are caused by the inflammation, and are not the cause of it: the treatment is the same whether they exist or not. In some cases we have profuse leucorrhœal discharge, in others none at all: this depends upon the extent to which the cervical mucous membrane is involved in the inflammatory action.

In regard to the treatment, as I have said before, these cases are often very obstinate, and many of them go the rounds, and months and years go by and the lumbo-sacral back-ache is always there. Still, notwithstanding this discouraging picture, I believe if the patient is willing to follow your directions, and is content to wait a reasonable time for results, you will be able to reduce the most densely hypertrophied cervix to a healthy condition. If the case has been under treatment before you are called to the patient, the chances are that she has had solid

nitrate of silver applied once a week for a longer or shorter time; it matters not which, for the hypertrophied and indurated cervix may be touched with nitrate of silver every week till doomsday without reducing its size. In order to substitute a healthy reparative inflammation for an unhealthy, unmanageable condition, you must cauterize; and nitrate of silver is not a cautery: it acts in these cases as little more than an astringent; the most it does is to cause a slight shedding of the epithelium. You do not apply the powerful cautery to reduce the size of the uterine neck by destruction of the tissue by burning it away, but you apply it to set up a subacute inflammation, under the influence of which the induration and hypertrophy will subside and the uterine structure resume its healthy elasticity. The strong caustics most frequently used in these cases are the acid nitrate of mercury, potassa cum calce, potassa caustica, and the actual cautery. As the last is the only one I ever use, I will describe the manner in which I use it, without further reference to the others. The idea of the actual cautery is always alarming to the patient, and may be said to remind us of the mediæval tortures; and if we were obliged to use live coals, bellows, and red-hot irons, I fear we should get few women to submit to the treatment; but by the use of these little sticks of charcoal, that I show you here, you are able to do away with all that is alarming about the actual cautery, and to apply it to the uterus without informing the patient what kind of an application you are about to make. These little sticks are made of nitrate of potash, charcoal, and pulverized acacia, in the following proportions:

℞ Potass. nitrat., gr. xx;
Carbo ligni, ℥vij;
Pulv. acaciæ, ℥j;
Aquæ, q. s. M.

This paste is formed into sticks; the most convenient size I have found to be about two inches long and about as large around as the little finger: the ends of the sticks may be rounded to a point; after being allowed to dry they are ready for use. If you hold the end of one of these sticks in the gas-flame for a moment, you will convert from half to three-quarters of an inch of it into a live coal: this you can do in another room, thereby avoiding the display of combustion before the patient. When once the end of the stick is thoroughly ignited you can put it down until you are ready to use it, without any fear of its going out, for it will continue to burn until the entire stick is consumed, which will require for a stick two inches long from fifteen minutes to half an hour. The patient being placed in a proper position, you introduce the speculum, which must be a conical one, and may be made of wood, ivory, or block tin; and I have often used the ordinary glass speculum. There is not heat enough from the caustic to do any harm if a glass one is employed; but the wooden one that I here show you is the one I prefer. Having introduced the speculum and wiped the cervix dry, you take the caustic in the forceps and apply it, about four or five lines from the os, to the lip that is most hypertrophied (for in some of these cases one lip of the cervix will be three or four times the size of the other). Now, if you make slight pressure for a few seconds, you will destroy the tissue over a space of about the size of a three-cent piece and for about two lines in depth. The pain is very slight,—but little if any more than that caused by the application of nitrate of silver. On withdrawing the cautery I sponge the parts with cold water. I then introduce a pledget of cotton saturated with glycerin, and direct the patient to remain in bed for the next forty-eight hours, and to keep her room, reclining on the lounge for the greater part of the time, for three days more. At the end of the first twenty-four hours you may remove the pledget of cotton by pulling upon the thread, and then inject the vagina with cold water; this may be done every day, until the slough comes off, which is generally in from five to eight days. I then paint the cervix every fourth day with the following:

℞ Potass. iodidi, ℥ss;
Iodinii, ℈iv;
Glycerinæ, ℥j. M.

The actual cautery may be applied with advantage once every month, and the best time is from five to ten days after the cessation of the monthly discharge. If you have the full co-operation of the patient, you will be able to reduce the most densely hypertrophied cervix in from three to five applications. In regard to danger from the use of the actual cautery, of course it would be very easy for a bungler to do harm with it, and great care should always be exercised in the use of any caustic: so far, I have never had any difficulty with it, and I have been using it for several years, and believe it to be more manageable and less likely to do harm than the potassa fusa that is so often used in these cases. I wish you to understand that I only recommend you to use the actual cautery in those cases in which the parenchyma of the cervix is the seat of hypertrophy and induration intractable to agents of less power.

ORIGINAL COMMUNICATIONS.

TWO CASES OF CIRCUMCISION.

BY W. H. WINSLOW, M.D.

A HEALTHY, robust man, æt. 27 years, a cooper by occupation, unmarried, who said he had never been sick in his life, and who had passed through the battles of the Wilderness unscathed, applied for relief from a very much contracted preputial orifice. He stated that he could always retract the prepuce behind the corona glandis perfectly, until recently; that he had never had any disease about the penis, and that the foreskin had been gradually contracting since six weeks before, when he had noticed, after a night of sexual indulgence, that the margin was chafed, fissured, and swollen. This condition had increased in severity. There was a rough, scaly, cicatricial appearance of the foreskin, and it was thickened by subcutaneous

deposits of fibrin. The fissures were widened here and there, forming small ulcers, which were very tender and painful and discharged sanious pus.

There was a slight offensive puriform discharge from the interior, indicating retained secretions and balanitis, and the foreskin was so much contracted and puckered that a probe of one-eighth inch diameter only could be introduced. The foreskin above was thin and flaccid, and when urination took place it became bulbous, owing to the quicker ingress from the true meatus than egress from the narrowed orifice. This caused pain along the urinary tract; and he complained of distressing priapism whenever he was in the society of women.

There were no signs of herpetic eruption. The inguinal and other glands were normal, and no symptoms of specific taint could be elicited. I was at a loss to determine whether his condition was due to psoriasis, which it somewhat simulated, or to an inflammation produced by the primary lesions and kept up by the unhealthy discharges and the irritation engendered by the nature of his daily labor.

The phimosis called for an operation, and I therefore removed an oblique ring of the diseased foreskin, attached the mucous membrane to the derma along the edges by sutures, and controlled the rather free hemorrhage by ice. The under side of the corona was covered by the mucous membrane one-eighth of an inch anterior to the edge, partially obliterating the frænum,—probably from balanitis; but its edge and depression behind were in normal relation upon the dorsal aspect. Recovery was rapid and satisfactory.

Another young, healthy man, æt. 23 years, applied for treatment of a gonorrhœa which he had contracted three months previously, for which he had been treated unsuccessfully by several physicians, though he had taken medicines *ad nauseam*.

Upon examination, there was found an extreme degree of phimosis, which the patient said had been present since he could remember anything, and which was proved congenital by the subsequent operation. The opening in the foreskin would only admit the smallest probe, and considerable manipulation was necessary to introduce it, as the redundant skin made an indirect oblique valvular aperture.

The prepuce was adherent to the glans, except for a space of about one-fourth of an inch in diameter, just around the meatus urinarius, and upon squeezing the organ there was a copious puriform discharge. Urination was tedious and painful, and he said he suffered much from supra-pubic distress in damp weather, from which some degree of retention was evident. Occasionally he would have a heavy aching feeling in the lumbar and sacral regions, with formication along the calves of the legs, and a peculiar lightness of the heels. He stated that at such times it seemed as if his feet would fly upwards and backwards when he walked. At times, when he got much excited, this peculiar pain would occur, and pass away some time after the emotion, leaving him nervous and irritable. It was very evident that he suffered from spinal irritation and paroxysmal congestion, which ultimately might lead to paralysis and other evils. It was also evident that the failure to cure his clap had resulted from the malformation of the penis, which required operation.

A perpendicular incision was made through the foreskin, and each flap dissected around and backwards along the glans; but so dense and firm was the attachment that it was difficult to find the true limits of the tissues, and the glans was nicked and bled freely in several places.

The patient, having refused an anæsthetic, fainted when the dissection had reached the edge of the corona; and upon recovery it was deemed best to postpone any further dissection backwards. A portion of each flap was removed, leaving the foreskin with a clean circular margin around the glans; and, as there was no mucous membrane to attach to the border of the cutis, and the latter had retracted to the corona, it was dressed with cotton and Goulard's extract diluted, and the patient walked cheerfully home.

The next day, expecting to find a furious inflammation, I was somewhat astonished, upon calling at his boarding-house, to be directed half a square away, where it was found he was visiting his *fiancée*. The parts healed kindly, and in ten days treatment was begun for the gonorrhœa, from which he soon recovered with a very respectable-looking penis, the foreskin making a smooth surface from the edge of the corona posterior.

The spinal affection disappeared after a few weeks, under the use of the bromides and small doses of fluid extract of ergot; and eight weeks after the operation, upon picking up the *Ledger*, I had the gratification of seeing his marriage-notice; but my apples were partly ashes, from the fact that I was minus a portion of my fee.

743 South Twentieth Street.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. F. F. MAURY.

Reported by Dr. J. Wm. White, Resident Physician.

FOUR CASES OF EXCISION OF THE HIP-JOINT.

CASE I.—L. T., æt. 9½, was admitted to the Children's Asylum of the Philadelphia Hospital in the spring of 1869, suffering from ordinary coxalgia, with severe pain in the knee of the affected side. She was at first confined to her bed, lying with her leg drawn up, the knee thrown outward, and the foot in contact with the buttock; but she subsequently improved so that she was able to walk with a crutch, the thigh being flexed on the pelvis, and the foot abducted and everted.

In June a tumor appeared on the outer side of the thigh, about five inches below the anterior superior spinous process of the ilium. In July there was distinct fluctuation, the right buttock was atrophied, and the gluteal crease displaced; the thigh of the diseased side and the back could not be made to rest upon the same plane. In August the abscess opened and discharged its contents. Davis's apparatus was applied, and the child was enabled to walk about with some ease and comfort for several months; but in January, 1870, the formation of a second abscess on the side of the thigh was attended with much emaciation, debility, and

marked anæmia. A bursal inflammation over the left elbow, followed by extensive suppuration, also aided in weakening and depressing her, and her general condition steadily deteriorated until November, when she was seen and examined by Dr. Maury. Both abscesses had left sinuses, into the outer of which a probe passed upward, outward, and slightly backward for four and a half inches came in contact with dead and eroded bone. A similar result was obtained by probing from the anterior and inner aspect of the thigh. Distinct crepitus was both heard and felt when the limb was moved, the great trochanter was displaced upward so that its superior margin was almost in contact with the ilium, and the thigh was much atrophied, its circumference at the middle being only eight inches, while that of the sound limb at a corresponding point was eleven inches. There were, however, considerable thickening and induration about the hip.

Iron and quinine were administered; she was placed on a generous and nutritious diet, and on December 10 Dr. Maury excised the hip-joint, in the presence of Drs. Allen, Pancoast, Brinton, Ashhurst, Packard, Freeman, Townsend, the resident staff of the hospital, and a large clinical class.

Operation.—The child having been brought under the influence of chloroform and placed upon her left side, a double-S-shaped incision, eight inches in length, was made through the skin and subcutaneous tissue on the outer side of the joint, commencing near the upper margin of the dislocated trochanter major, and extending downward. A second incision down to the joint laid open the capsular ligament; the limb was strongly adducted, and drawn upward, and the head of the femur, rendered prominent by these means, was then taken off by cutting through the bone with a chain-saw just below the great trochanter. The outer surface of the femur, the trochanter minor, and the entire acetabulum, being carious, were removed in the same manner, leaving quite a large orifice in the pelvic wall. Only about eight ounces of blood were lost, and no vessels were tied. An hour later a tent of picked lint saturated with sweet oil was inserted into the wound, which was closed with six silk sutures, and a silicate-of-soda dressing was applied, leaving the projecting tent and the dependent angles of the incision uncovered so as to allow free drainage.

A quarter of a grain of morphia and half an ounce of brandy were given at once, and hourly doses of a tablespoonful of beef-tea with a teaspoonful of brandy were prescribed. In the afternoon her pulse varied from 130 to 140, her skin was moist and warm, and there was slight oozing of bloody serum from the wound. During the night a little hemorrhage occurred, but was promptly checked by the application of ice.

December 11.—Pulse 152; skin hot, but moist; child lay with the leg flexed on the thigh, and the thigh on the abdomen, seeming to be more comfortable in this position than in any other. There was still some serous oozing from the wound, at one extremity of which a slight blush had appeared. The buttock was painted with an ointment of oxide of zinc, and a fever mixture of sweet spirit of nitre and acetate of ammonia was ordered. In the evening a sixth of a grain of morphia was given.

December 12.—Pulse 148; temperature somewhat lower; the silicate-of-soda bandage was removed, and the wound found to be in a healthy condition. There was at this time considerable distention of the abdomen, with hypogastric pain and tenderness, but emptying the bladder gave immediate relief.

December 13.—Pulse 152, and irregular; suppuration had commenced, and the wound was not offensive, but the pus was drab-colored, thin, and scrofulous. She was still taking brandy, beef-tea, and milk in large quantities, and in addition a mixture containing quinia and the muriated tincture of iron.

December 15.—Pulse 140; wound suppurating freely, about one inch having united by first intention; the dressing was renewed for the first time since the operation, and in the evening the bowels were opened, also for the first time. She continued to take a sixth of a grain of morphia at night, and rested tolerably well.

December 18.—Pulse 128; skin warm and moist, and free passage from the bowels; general condition excellent. The pus escaping from the wound had now become thicker and more creamy, and was very abundant.

On December 23 she was able to extend her limb unaided and without pain, and from this time progressed steadily towards recovery. In twelve weeks she was walking about with the aid of crutches, and was enjoying excellent and almost vigorous health. The shortening which remained permanently was only two and a half inches.

Case II.—G. K., æt. 9, born in Maryland, was admitted to the Children's Asylum of the Philadelphia Hospital in March, 1871. His father died of phthisis pulmonalis, but his mother and several brothers and sisters were all living and healthy. Two years previously he had had a severe attack of malarial fever, followed by a gradually increasing stiffness of his joints, which finally obliged him to use crutches. At the time of his admission he was much emaciated, had no appetite, walked with great trouble, and was suffering from an otorrhœa; general appearance decidedly strumous. There was a profuse discharge from a sinus situated in the left hip-joint just below the great trochanter. He improved under treatment until October, when he had an attack of remittent fever; he was placed upon quinia, lacto-phosphate of lime, and cod-liver oil, and soon grew better.

On November 22, Dr. Maury brought him into his clinic in the presence of the attending surgeons and resident staff of the hospital, and a full class. He was then able to walk about the room with crutches; the heel of the left foot was drawn up, the toes alone touching the ground, and the knee was strongly adducted, almost in contact with the sound thigh. The shortening was two and a half inches. There were three sinuses about the joint, one lying over the trochanter major, still discharging and leading to dead bone, another over the sacrum, and a third, anterior and quite patulous, the probe passing in its entire length, in the direction of the acetabulum.

Operation.—The patient having been completely anæsthetized with chloroform, Dr. Maury made an S-shaped incision immediately over the joint and extending through two of the sinuses. The limb was forcibly adducted, the head of the femur freed from its attachments to the dorsum of the ilium, and removed by means of a chain-saw; a second piece was taken from the shaft of the bone, the whole portion excised measuring four inches and three-quarters. The endeavor was made to save as much periosteum as possible; but all except a small portion was so markedly diseased that it would have hindered rather than aided the reparative process. There was little or no hemorrhage, and no ligatures were required.

The wound was closed by five interrupted sutures, and dressed with adhesive strips; brandy and morphia were given as soon as the effects of the anæsthetic disappeared, and a febrifuge mixture was prescribed. He was allowed to assume any position he desired, no restraint whatever being put upon his movements.

November 26.—The limb was straightened and placed between sand-bags, the operation causing considerable pain. A solution of permanganate of potassa was ordered as a wash for the wound, which was looking healthy.

November 28.—No fever; very little pain; appetite good; bowels opened naturally. Suppuration was taking place, and there was a free discharge of laudable pus from the wound.

December 2.—The boy was anæsthetized, and extension was applied to the limb by means of adhesive strips. This was continued until the middle of January, when it was removed, and the leg was allowed to lie between sand-bags. Recovery was somewhat retarded by the formation of an abscess on the inner side of the thigh, but by the end of March the patient could flex and extend the limb without any difficulty. The general condition was much ameliorated after the operation, and remained excellent until he was able to walk around with crutches, and the cure was complete. The shortening in this case was about three inches.

(To be concluded.)

PHILADELPHIA HOSPITAL.

CLINICAL SERVICE OF DR. H. C. WOOD, JR.

Reported by JOHN M. KEATING, M.D., Resident Physician.

STHENIC PNEUMONIA—ITS TREATMENT.

A. D., æt. 39, was admitted to the hospital on Saturday, August 30. She stated that after exposure to wet she was seized four days previously with a severe pain under the left breast, which interfered much with breathing. This stitch continued for two or three days, during which time she was not confined to her bed, and was then felt in the same position on the right side. When admitted on Saturday her temperature was 103°: her pulse, full, strong, compressible, was beating 120; respirations 34. She complained much of the difficulty in breathing, and the pain in the right side. Over six ounces of blood were ordered to be taken by cut cups from the posterior lower portion of her lung, warm poultices to be placed over her whole chest and changed frequently, and the following mixture was given her, a dessertspoonful every two hours:

℞ Tinct. veratri viridis, ♏xx;
Liq. ammon. acetat., f℥ij;
Spts. etheris nitrosi, f℥j;
Liq. potass. citratis, f℥ij.

The veratrum viride was added to the mixture as it was not thought advisable to allow the nurses to administer it separately. When seen by Dr. Wood on Monday, there was dulness on the right side, with fine moist râles; on the left side there was blowing respiration, with fine crackling râles. The doctor stated that he brought her before the class to-day to speak more at length upon the treatment of this disease than upon its symptoms. "It must be understood that pneumonia does not always present the same phases; that whilst the pathologist is justified in calling all cases which offer certain anatomical changes pneumonia, to the therapeutist they are very diverse,—in a word, that pathological unity and therapeutic diversity often go hand in hand.

"The present case is apparently of that variety known as acute sthenic pneumonia: the ordinary pneumonia of young and robust subjects, characterized by its sudden onset after exposure, its sudden rise of temperature, which in a few hours may reach 103° or 104°, its headache, flushed face, strong, hard pulse, and hurried respiration. In it, after a time, sudden apparent convalescence occurs: a sudden fall of temperature, amounting may-be to five degrees, on the third, or sometimes on the ninth or twelfth, day. In the present case some of the elements for diagnosis are wanting, as the history is rather imperfect; none of it can be relied upon, and the patient was not seen until the fourth or fifth day. It is, therefore, difficult to say whether there will or will not be a distinct crisis; but I believe there will be. Sometimes, especially in patients broken down by poverty or dissipation, such as we see so many of in this house, there is a gradual defervescence, and the pneumonia becomes chronic. When the temperature falls, you have left the consolidated portions of the lung, and nature proceeds to relieve this gradually by converting the fibrin into soluble mucin, some of which is coughed up and the rest absorbed to allow the lung to resume its normal condition. In most instances of frank pneumonia there is a tendency to recover, and rest alone will often be all that is needed.

"In the majority of cases, then, of sthenic pneumonia, medical interference is not necessary for cure, although probably always if properly directed it will shorten the period of sickness. The question at once comes up, Can you arrest the disease? Personally I have no doubt that although pneumonia is a cyclical affection, it differs from the fevers in that if taken in the onset it may be sometimes stopped. I believe this because I have seen free bleeding do it. In many cases, however, venesection will fail of the desired end, and it may do fatal injury if it does not stop the disease, by leaving the patient unfit to bear the exhausting processes of recovery. Bleeding, therefore, for the purpose of arresting pneumonia is accompanied by too much risk.

"The old classic treatment was to bleed, give antimony, and blister. We can now replace the bleeding and antimony by veratrum viride or aconite, both of which reduce at once the force and frequency of the pulse and lower the temperature; but veratrum viride is safer and more controllable than aconite, and if by chance your patient should get an over-dose its ill effects are much more easily controlled by whisky, etc. One or two or three drops of the fluid extract every two or three hours until the pulse and temperature are impressed may be given, watching carefully as you give each dose. It is better, when you can do so, to give it separately. Use locally large poultices. Blisters increase fever when there is great arterial excitement, and do more harm by their constitutional action, than good by their local influence.

"Poultices, by relaxing the capillaries of the skin and by the irritation of their heat, cause an afflux of blood to the surface, and therefore act as mild counter-irritants. Moreover, I think they very probably, even in adults, influence the lung itself directly, just as they do a boil or inflamed external part. In children the chest-walls are so thin that it is exceedingly probable warm water will slowly find its way through them. Be this as it may, poultices are the best local application in the hot stage of pneumonia, and I habitually continue their use until the lung has well cleared up; although some prefer blisters after defervescence. In my practice the epispastics are reserved for those cases in which the consolidation tends to become chronic.

"After defervescence, annoying symptoms, such as cough, sleeplessness, etc., may be treated; but the chief indication is for support whilst the exhaustive process of clearing up is being carried out. At this time, then, withdraw the veratrum viride, and put your patient upon tonics and nutritious, easily-digested food. Of course, the best food you could give would be blood and raw meat; but in lieu of these, as they are objectionable to the patient, use *milk*. Lime-water is added, to make the clot spongy and soft. You can now treat slight symptoms: blister, if you wish; I never do it, except when the disease shows a tendency to become chronic. Such is the usual plan of treating pneumonia. But there are some cases which urgently demand immediate attention. The case before you, when she entered the ward, was gasping for breath. Consequently the blood-

paths were greatly narrowed by the obliteration of so many capillaries, and congestion of the sound portions resulted,—a congestion which was a mere physical result, but demanded immediate relief. There was consolidation of a large part of one lung, and the other was also affected, because there was too much blood for passage, and instant relief was demanded.

"When there is intense collateral congestion of the lung in pneumonia, reduce the volume of the blood in some way. The best way to do this is to bleed by the arm. In the present case it was thought proper to use cut cups, as the day she entered was the fourth day of the disease. When the pressure of the blood upon the vessels is increased, there is a tendency to leakage; and œdema of the lung complicates the existing trouble. Never *dry*-cup in pleurisy, as post-mortem examinations show that the contiguity of the pleura causes it to increase instead of diminishing the congestion.

"The future of the case before us is doubtful, and no certain prognosis can be made. Alcohol is demanded when there is failure on the part of the circulation. Alcohol is in large doses a febrifuge, but is, besides, the most powerful arterial and vital stimulant; and the great indication for its use in pneumonia is failure of vital power and of circulation. These seem now to exist in our case, and she shall be put on the use of alcohol."

[The woman was put upon the use of three fluid-ounces of whisky in the twenty-four hours, the veratrum viride withdrawn, and fifteen grains of quinine exhibited daily. The day after the clinic her temperature fell from 104° to 99½° F., and under supporting treatment the case has since progressed steadily towards convalescence.]

BELLEVUE HOSPITAL, NEW YORK.

NOTES OF TREATMENT.

INTERMITTENT FEVER.

SOME preparation containing quinine is usually given by all divisions in the treatment of this disease. The following, "Clark's powder," is given almost exclusively on the third division:

℞ Pulv. opii, gr. j;
Pulv. capsici, gr. iij;
Quin. sulph., gr. x. M.
S.—Dose.

This is given about four hours previous to the time the chill is expected. If admitted during a paroxysm, or shortly after one has ceased, the powder is given and repeated as above. This rarely fails to break up even a prolonged series of paroxysms, and in recent cases almost invariably succeeds. By others, quinine alone is administered. The patient is rapidly brought under its influence in the following way: If the chill be expected in the morning, quin. sulph. gr. x are given the night previous, and again in the morning, one dose four hours, another dose two hours, before the time the chill is expected to occur. In the majority of cases this is successful in warding off the chill. If, however, it occur, a hypodermic of morphia is sometimes administered; but oftener the above dose (gr. x) is repeated in the hot stage, and quinism produced and maintained until the disease yields. In addition to this, some preparation of iron is given, as tr. ferri chlorid. ♏ x–xxx t. i. d. The hypodermic administration of quinine is being used extensively here, usually with favorable results. The solution adopted is the following, suggested by Dr. F. D. Lente, of Cold Spring, New York:

℞ Quiniæ sulph., gr. 1;
Acid. sulph. dil., q. s.;
Aq. ebullient., ℥j.

Allow this to cool; then add—

Acid. carbolic. (cryst.), gr. iv. M.

Of this, ♏x–xxx or more may be injected subcutaneously without danger of producing abscesses, such as commonly arise by the use of the ethereal solution. Dr. Lente states that, although he has used it constantly in his practice, he has never seen an abscess caused by it; and a similar experience has attended its use here. This method is especially useful in cases of coma into whose causation malaria is suspected to enter; also in cases where it is necessary to bring the patient rapidly under the influence of the drug.

When quinine fails to arrest the paroxysms, arsenic is employed. A patient with malarial neuralgia of several weeks' duration had been treated by quinine in all the methods recommended, with no beneficial effect. Liq. potassæ arsenitis ♏viij t. i. d. put an end to the trouble in two days, the patient being discharged cured in ten days.

HYPERPYREXIA.

If malarial, this is treated by quin. sulph. gr. v, q. 4 h., and even in diseases in which no malarial element exists quinine is given. A temperature of about 104° F. is usually treated by quinine as above, and by tinct. aconit. rad. (Fleming's) ♏j, q. ½ h. for three or four doses, then q. 1 h. In sthenic inflammation this is the most common method, and is usually successful. If the temperature rise above 104° F., sponging the surface with water is employed, somewhat differently on different divisions; some preferring cold, others tepid water. Several cases of insolation were treated on one division as follows: by means of an ordinary garden-sprinkler, water as hot as could be conveniently borne was sprinkled over the body, an attendant on each side of the patient fanning the surface vigorously meanwhile. By this means the temperature in all cases rapidly fell, and did not show the same tendency to rise immediately that is observed when cold water is used. Ice-bags to the head, and cold-water injections into the rectum, were also used in some cases.

DIPHTHERIA OF WOUNDS.

Several cases have occurred during the past month in the lying-in-wards of diphtheria of wounds of the mucous membrane acquired during labor. The practice has been in almost every case to cauterize the surface with argent. nitrat. fus., and to apply cloths moistened with "black-wash" to the wounds. In one case cauterization was adopted, and no other local application made, the parts being syringed out thrice daily with sol. acid. carbolic. (gr. x–℥j). Resolution quickly followed in the last, and in all the others except one, which was complicated with puerperal fever. In all cases of fetid lochia, injections are employed either of the sol. acid. carbolic. or infus. chamomil.

W. H. Farrington, M.D.

TRANSLATIONS.

A CASE OF MELANÆMIA.

By Dr. S. Von Basch. Translated from *Wiener Med. Jahrbücher*

BY WILLIAM ASHBRIDGE, M.D.

THE patient whose case is here reported was a physician, 32 years of age, practising his profession in a very malarious region, who up to the year 1868 had always enjoyed good health, with the exception of attacks of muscular rheumatism of but little severity. In 1868 he had an attack of intermittent fever, which was speedily cut short with quinine. In the following

year the attack was repeated; in 1870 and 1871 the attacks become more frequent and of longer duration, but somewhat diminished in intensity. In the spring of 1872 the frequency of the attacks increased so much that the intervals between them were never longer than ten or twelve days. The types of the paroxysms were varied in character. The attacks in the beginning of May, 1872, were accompanied at one time with crural neuralgia, at another with pain in the muscles of the neck and back, and in both cases the pain ceased together with the intermittent fever on the administration of quinine.

Towards the end of July of this year, a new feature made its appearance. The patient began to feel a peculiar burning sensation in the fossa navicularis, which increased in intensity during urination, accompanied by a feeling as if the bladder was not completely emptied of its contents. A few days later, to the pain in the urethra was added pain over the symphysis; and about two weeks after this, intense pains in the joints, accompanied by a fever, set in, and lasted with about the same intensity for three days, when, under the use of cold water externally, and large doses of quinine, these two last-mentioned symptoms vanished. The symptoms before mentioned, however, continued, and a certain periodicity was observable in their recurrence: beginning in the course of the forenoon, they reached the maximum of their intensity about four or five o'clock P.M. The urine passed in the course of the day, with the exception of a slight cloudiness due to mucus, presented nothing abnormal; that, however, passed in the evening presented a milky cloudiness as it issued from the urethra, and upon standing there was precipitated from it a plentiful sediment of a dirty white color, which was soluble in acetic acid. This state of affairs continued, with occasional intermissions, due sometimes to large doses of quinine, at others of spontaneous origin. In the commencement of August the patient was sent to Marienbad; but the use of the waters was found to augment his sufferings, and the sediment in the urine continued as before. A short time after beginning the use of these waters, he came under the care of Dr. Von Basch, presenting at that time a marked cachectic appearance, and the spleen and liver were found by percussion to be enlarged to a marked extent.

The suspicion that the symptoms of trouble in the urinary organs might be due to the existence of a vesical calculus was entirely set at rest by a careful examination, so that, from the history of the case and the condition of the patient at this time, it appeared that the trouble was due to some disturbance of nutrition, having its origin in the repeated attacks of malarial fever to which he had been subjected. In his treatment of the case, Dr. Von Basch forbade the further use of the mineral waters, believing from what he had seen of their effects that they could only do injury, and, feeling convinced that the malarial influence was still active, ordered larger doses of quinine, with the expectation of continuing them for a considerable length of time. He advised at the same time the use of baths containing carbonic acid, since it has been found that the absorption of oxygen is favored by bathing in waters containing an irritant to the skin, hoping that a more active metamorphism of tissue would act favorably upon the malarial process. The result of this treatment was, on the whole, favorable; for the neuralgia and the sediment in the urine were absent more frequently than previously. The microscopic examination of the blood, which was commenced in the second week of treatment, supported the supposition as to the malarial origin of the trouble.

In the urine were found crystals of oxalate of lime, crystals of uric acid, and flakes containing a dark-brown pigment. From this Dr. Von Basch was induced to examine the blood of the patient, and in it he found similar hyaline flakes, and bodies resembling cells containing pigment. By this examination the existence of melanæmia was established, and its dependence upon malarial cachexia has been fully demonstrated by many observers. It is important to notice that in this case the urine contained no albumen, while in those cases already reported, in which this pigment in the urine was found, that excretion contained albumen.

In regard to the source whence the pigment came, none other than the blood can be given.

In support of this, the facts that the pigment was found in the recently discharged urine, and the entire resemblance between that found in the blood and urine, can be adduced. The well-known state of kidneys in patients with melanæmia renders it probable that the pigment passed from the blood into the urine within these organs, and not that it made its exit from the blood-vessels of the bladder. In conclusion, it is to be noticed that none of the other constituents of the blood were to be found in the urine, although the size of the pigment-flakes was from two to six times greater than that of the white blood-corpuscles. The condition of the patient gradually improved, until at last the symptoms had ceased, his health was good, and he was gaining in weight; but the pigment was still to be found in the blood and urine.

Upon his return to his home, however, a new attack of intermittent fever came on, and all the other symptoms detailed above returned.

MYOSITIS OSSIFICANS.

By Prof. Podrazki. Report of a case presented to the *K. K. Gesellschaft der Aerzte in Wien*, April 18, 1873. Translated

BY WM. ASHBRIDGE, M.D.

THE patient was a soldier, in whom as a result of excessive gymnastic exercise a development of bone had taken place in the brachialis anticus muscle of the right arm. This process had gone on with surprising rapidity, for at the end of eight days' exercise a swelling quite hard and tender could be discovered in the region of the muscle referred to. At its commencement the tumor was distinctly elastic, was undoubtedly situated in the belly of the brachialis anticus muscle, pretty firmly adherent to the humerus, and with the tendon of the biceps running over it. The arm was bent in a right angle at the elbow, and could neither be straightened by the efforts of the patient nor by passive motion. At first a strong needle could be thrust into the tumor, giving the sensation derived from a similar procedure with cartilage, and not causing the patient any pain. The tumor remained for a period of three weeks, when under the influence of chloroform an attempt was made to extend the arm. The contraction finally yielded to the efforts of the operation, giving rise to a tearing sound, supposed to be due to the separation of the tendon from the muscular tissue. The arm was placed upon a splint kept straight for some days, and from that time the motion in the elbow-joint was freer, but the muscle became constantly harder, and finally as hard as bone itself.

At the time the patient was shown, it was impossible, even with great force, to thrust a needle into the tumor, but the formation of bone could be distinctly recognized.

Two similar cases were presented by Von Pitha in 1864; the patients in both cases being soldiers, and the affection appearing in the same muscle, but in both cases upon both arms. A case entirely similar to the one here described is alluded to in the "Handbuch der Chirurgie" of Von Pitha and Billroth.

PHILADELPHIA
MEDICAL TIMES.
A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,
715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 13, 1873.

EDITORIAL.

OUR HOSPITALS FOR THE INSANE.

AMONG the medical institutions of this community, none show signs of greater prosperity—meaning thereby an enlargement of their material resources—than our hospitals for the insane. Not only are they used nearly up to the limit of their capacity, but they have been recently enabled, through their own income or the special contributions of their friends, to meet the requirements of the time by extending their capacity, by providing a more liberal style of accommodations, and by increasing their means and appliances for the promotion of comfort and recreation.

First and foremost, the old Pennsylvania Hospital for the Insane, which, thirty years ago, obtained a new location beyond the Schuylkill, with ninety-seven patients, which number has now grown to four hundred and more, will begin the coming year with room for an additional thirty, in a new building, erected, like a similar one four or five years since, by means of the Fisher bequest. The one just finished is an admirable specimen of hospital architecture, providing for every requirement in the most satisfactory and pleasing manner. Though plain enough for the strictest economy, it is all in good taste, and not without some show of elegance; while the work and the materials are unexceptionably good. Thus, from time to time, this noble institution has been enlarging its means of usefulness, and every time presenting a fresh memorial of the enlightened benevolence of this community.

The old establishment at Frankford—the first in this country to exemplify, independent of other connections, the better management of the insane introduced by Tuke in England and Pinel in France—has lately yielded to the demands of the time for more and better accommodations, by erecting additional wings, by putting on another story in the Mansard style, and by various architectural changes that have greatly improved its appearance without and within. If beautiful grounds and fine rural surroundings fit an establishment in any measure for treating the disordered mind, this is singularly fortunate; and that these attractions, in connection with the above-mentioned improvements, are having their legitimate effect is well shown by the increasing number of patients,—larger the present season than ever before. In this wider field of usefulness, we doubt not, it will continue to maintain the reputation already earned as the successful pioneer in this benevolent work.

The private hospital of Dr. Given, near Kellyville, also illustrates the progressive spirit of the time, in a new Mansard roof, which gives it considerable additional room, and imparts a feature of elegance to its outward aspect. This institution has more patients at present than at any previous period; and if untiring devotion to his duties, intelligent and unceasing endeavor to promote the comfort of the unfortunates committed to his care, and constant personal supervision of his wards, should insure increasing numbers, the doctor well deserves success. Private asylums have provoked much unfriendly criticism, but there is, notwithstanding, a certain demand for them in our affluent communities, which *will* be supplied, and Dr. Given's is one of the kind best fitted to meet this imperative want. Its location is favorable, commanding a very extensive view, its grounds are beautifully planted, and, while exempt from vulgar intrusion, it is always open to the intelligent visitor to inspect and examine.

Let us mention, by the way, that many of the patients in these hospitals are from other States,—especially from the South and West. The fact furnishes a signal proof of that pre-eminence which Philadelphia has ever maintained in the attainment and diffusion of medical knowledge, and its results. People would not bring here their insane friends hundreds of miles from home, except upon the firm belief that they would receive, in a higher degree than they would anywhere else, the benefits resulting from the latest advancements in science, ren-

dered practical and enduring by private munificence.

We have another hospital, with twice as many patients as all these together. We refer to the Insane Department of the Philadelphia Almshouse, now containing over one thousand patients. Some three years ago the municipal authorities, at the instance of some benevolent gentlemen who were dismayed by its crowded condition, ordered the erection of two more buildings, one for each sex, capable of accommodating about seventy persons each; that is, providing for a two years' increase, as for the last six or seven years the admissions have exceeded the discharges at the rate of about seventy per year. The measure was prompted by the most benevolent motives; but it reminds us of Dame Partington's attempt to sweep back the Atlantic Ocean with a broom. At this moment there is more need of two additional buildings than there was three years ago. Now, as then, the patients are closely crowded together, with little or no employment, and at night many of them are put away in rooms six feet by ten at the rate of three in a room.

But then these patients are nothing but paupers —guilty of the double crime of poverty and insanity. All praise, then, to our City Fathers for crowding them into apartments too small for half the number. Millions upon millions must be furnished for the new public buildings. In the day of our city's exaltation, when Europe and America crowd its streets because a mighty nation celebrates its hundred years of freedom, it is well that, stone upon stone, marble upon marble, our municipal palace shall stand in cold but glittering magnificence.

Asking God's blessing, then, on our enterprise, let us for its furtherance strip our city hospital of every convenience; let every appliance for relief be withheld, every hope of cure banished, every mitigation of the deepest agony the human soul can suffer this side of eternity be sternly put away. All praise to those who have learned how to take care of our pauper insane at one dollar and eighty-five cents per week,—just enough to keep off the pangs of hunger with the coarsest possible of food; just enough to keep out the winter's cold with the coarsest possible of clothing. It is well—Dives should fare sumptuously, but let Lazarus with thankful heart kennel with the dogs in the stable.

Dr. Braxton Hicks, of London, has so nearly recovered from his severe illness, caused by an infectious wound, that he will return speedily to his ordinary duties.

RAPTORES ET OSCINES.

NOT long since we came across an educated citizen of no mean country,—China,—whose companion and purse-bearer had been murdered and robbed in New York, and who, penniless and without knowledge of our language, found his way to this city by hook or by crook, because, as he has since said, some "teachee man" had told him in China "nobody but good people in Philadelphia." Judging from the letter which we publish in another column, our city's reputation is better abroad than at home,—better in China than in Washington County. Yet we think this Munce affair may be deemed unfortunate rather than culpable, at least when judged by the political standard of our times. Our correspondent, if he be a voter, must know that, whatever the theory of our city government may be, in practice, like the class Aves, we are divided into two sets, those of prey and those to be preyed upon, —the rapacious birds and the finches,—the politicians and the people. The citizens know it, yet prefer, apparently, to be swindled, since they could alter matters if they chose. Under these circumstances it seems rather hard to call, as has been done, a poor coroner's driver a "ghoul" because he imitates his betters and robs the dead, or to revile the superintendent of burying-grounds because he pockets eight dollars extra from the tax-payers whenever he gets a chance. Why howl at the little rogues, when year after year the great rogues are re-elected,—yea, fawned upon? Shall not the tax-payer enjoy his inestimable privilege of being plundered? The ado, then, about these "small fry" has amused us exceedingly, and we have been only more amused by one thing, viz., the idea that any man should be so innocent as to think that our "learned District Attorney" will hurt any one of his following in this matter, unless, indeed, so much outside pressure be put upon him that he fears for himself.

So far as the medical authorities are concerned, we do not see that any blame attaches to them. When a body is brought by the properly constituted authorities to Dr. Hodge, with regular certificates, on what plea shall he refuse it, or why shall he ask whether it has been kept the forty-eight hours required by law? If he does ask, how is he to prevent men who have told a legal lie on paper from supporting it by an irresponsible verbal one?

So far as preventing similar occurrences in the future is concerned, the embalming and preserving of the bodies for a month or six weeks at the Morgue strikes us as the best proposal. As for "honest officials," the day for that has passed.

Whilst we are writing upon this subject, a few words in regard to the condition of the old University building sold to the United States government may not seem out of place. As is known to most of our readers, in the cellar of the building spoken of are a number of vaults or pits, nine, we believe, in which it has been customary for many decades to store the débris of dissection, filling a pit one year and closing it until, at the end of eight years, its turn comes again. The cleaning of these pits is a matter involving some thousands of dollars; and, as the government was informed of their presence before the sale and transfer of the property, no blame can be attached to the University trustees for not incurring the expense of emptying the vaults. It appears, however, that the medical faculty or its officers did not properly clean up the building; bones, and even partially dissected bodies, were left in various portions of it, instead of being placed in the pits, and gave rise to an odor which caused an official visit of the Board of Health and gave a pretext and inducement to burglarious reporters to break into the building at night, or more probably to imagine that they had so done, and to sicken the people with horrible sensational stories of what they had seen.

A great deal of censure is due those whose carelessness has given occasion for so much reproach; but at least as much reprobation is owing to such papers as the *Press*, which prostituted what influence they may have to excite public opinion against the medical schools. On the other hand, the thanks of the profession are due to the *Evening Bulletin*, the *Public Record*, and some other papers, for the sensible manner in which they have discussed the question.

CORRESPONDENCE.

LONDON LETTER.

[*From Our Own Correspondent.*]

The Medical Vacation—Doctors in the Highlands—The Meeting of the British Medical Association—The Members—The Cost—The Orations—Mr. Wood's Failure—Aspiration—Foreigners present—The Sources of Strength of the Association—Sir William Gull's Absence—A Thousand New Members—The *Times* and the Medical Journals.

AUGUST 18, 1873.

THE medical "season" here closes definitely at the end of July, and from that date until October, when the schools reopen and the work of the winter session recommences, we have a sort of interregnum. All London is out of town, and the medical men take their vacation. Some of our leading men are famous holiday-makers. I write to you to-day from a distant part of Scotland; and near me in the Highlands are Sir Henry Thompson, Dr. Priestley, Dr. Quain, Dr. Wilson Fox, Sir William Fergusson, and I know not how many more. Dr. Quain is a famous shot, and his London house is adorned with a forest of antlers, the trophies of his prowess in the deer-forests of Scotland; Sir Henry Thompson is almost as skilled with the brush and palette as with the lithotrite and the knife; and before sitting down to write you this retrospective letter of the last weeks of the season, I have had the pleasure of filling a basket with speckled trout, which I would more willingly send you than this MS. if it were likely to give you as much pleasure as the sport gives to city-pent men who can only break away at annual intervals from the round of professional work.

The London season closed, however, with a great meeting, half of business and half of pleasure, which deserves some record. The London meeting of the British Medical Association has been a very great success. Some of your professional brethren in Philadelphia, Dr. Wistar and Dr. Solis Cohen, were with us, and may perhaps give you some notes of their impressions. Dr. Gross was specially invited, but was unable to come. Nearly two thousand medical men assembled; and the meetings lasted throughout the week. The British Medical Association is made up of twenty-one local associations or branches, each having its own local meetings and local organization (on a nearly but not quite uniform plan), and each sending delegates to the Council, and to the smaller executive body or Committee of Council which governs the whole Association and represents it during the year. The secretary of each branch is *ex officio* a member of the Committee of Council, and so are the Past Presidents of the Association, who on quitting office become permanent Vice-Presidents of the Association. The other members of the Committee of Council are twenty gentlemen elected by open ballot at the General Council at each annual meeting, and of whom a proportion must retire annually. Thus the Committee of Council consists of about sixty members,—twenty-one secretaries of branches, elected by the branches, twenty elected members, elected at the annual meeting, and, by a recent resolution, the readers of addresses, etc., for the year. It is difficult to devise a more thoroughly representative body; and accordingly it has been found to work, on the whole, in a manner highly satisfactory to the profession. The Association takes from its members an annual subscription of a guinea: out of this it contrives to pay the executive expenses of the General Secretary, who receives an annual salary of £350 a year; his clerks and expenses; the expenses of standing committees, such as the Medical Reform Committee, Parliamentary Bills Committee, State Medicine Committee, and others; and, besides this, to furnish each member with a weekly copy of the *British Medical Journal* free by post. That journal is the organ and property of the Association. Eight years ago it was a small but respectable journal of about twenty pages: it is now a large quarto journal varying from forty to fifty-six pages. The numbers of the Association have risen consentaneously with the im-

provement in the journal. Seven years ago there were not more than two thousand members of the Association: there are now nearly six thousand members, and each year brings its contingent of several hundred new members,—the present year most of all, for more than eight hundred new members have joined already, and I am told by the Secretary, Mr. Fouke, that enough to make up a thousand are awaiting admission.

So great a progress has naturally excited a great deal of attention. Mr. Baker, the President of the Association, and Dr. Quain, the President of the Metropolitan Counties Branch, have during the last few weeks officially ascribed the opening of the new era of prosperity for the Association, and its steady continuance, to the improvement in the *British Medical Journal* with which it has been coincident and contemporaneous. The Association has lasted now forty-two years: it numbered about fifteen hundred members within a few years of its foundation, and there it stuck for twenty-five years. It held great meetings in London, in Edinburgh, in Birmingham, and elsewhere, and gathered to itself large accessions of members; but there was not in the ordinary activity of the Association enough to retain the members, and the return for the annual guinea subscription did not seem sufficient. Thus its fortunes fluctuated: the increase of one year was followed by a falling off in another year. For the last six years, however, the increase has been continuous and persistent; and this dates from the time that the size of the *Journal* was doubled and that it was placed under vigorous management which has increased its receipts from advertisements from £600 a year to nearly £3000 a year, which has been spent on the journal itself. The increase in the numbers and influence of the Association has naturally imparted also more confidence and activity to the policy of its managers. It has compelled the government to issue a Royal Sanitary Commission, on the reports of which has been based the Public Health Act. It obliged the minister in charge of that act to accept certain modifications of it. Under that act a medical man is appointed in every district of the country, at a good salary, charged with important duties and large powers as an officer of hygiene and preventive medicine. It has compelled Mr. Stansfeld to promise to include the existing medical officers under the laws for the relief of the poor by organization, and to remunerate them adequately for their trouble. It has called Mr. Cornwell, the Secretary of State for War, to account for provisions in a recent army warrant which are considered to be less favorable than they should be to army medical officers; and it has obtained from him concessions which now await the assent of the Treasury. Mr. Stansfeld, the President of the Local Government Board, last week addressed Mr. Ernest Hart, the chairman of the Parliamentary Bills Committee, with a letter requesting him to frame for the consideration of the government a scheme for the education and registration of midwives,—a subject which was recently recommended to his attention by a deputation of the Association.

Thus the Association had already a large place in public estimation when it commenced its annual meeting on the first week in August. The Lord Mayor of London gave some *éclat* to the meeting by offering an evening reception at the Mansion-House to the members and their ladies, who mustered to the extent of about four thousand. The authorities of the Royal College of Surgeons and of University College rivalled the municipality in the liberality of their entertainments. It is the custom of the Association that the annual meeting is held by the invitation of the local branch resident in the town in which the meeting takes place. The Metropolitan County Branch accordingly bore the expense of the arrangements for the meeting. These included the fitting up of the building in which it was held, King's College, the provision of a free luncheon each day for all comers, and grants to the excursions and pleasure-parties with which the week ended. Not more than about one thousand members were expected, and to defray the expenses £800 were raised among the metropolitan medical men. This, however, falls short of the expenditure, which has not been less than £1200; and a further subscription is being raised. Altogether, the expenses fall heavily upon some members; for the more prominent members of the Association entertained largely at their own houses, at dinner, during the meetings. Sir William Fergusson, Sir William Jenner, Dr. Quain, Mr. Curling, Dr. Russell Reynolds, Mr. William Adams, Sir James Paget, Dr. Burrows, Dr. Morell Mackenzie, Dr. Andrew Clark, Dr. Wilks, and others, received parties of fifty and sixty; Mr. Spencer Wells gave a garden party to one hundred and fifty guests. Sir William Gull, Mr. Prescott Hewitt, and Sir Henry Thompson were conspicuous by their absence. They were unwilling to sacrifice the first week of their holiday. In the case of Sir William Gull especially, who owes much to the Association, this carelessness and neglect of his provincial brethren, by whom he has been largely aided to rise to his present position, is the subject of much indignant comment, and the more so that it has not, as in some other cases, been relieved by the expression of regret and by compensatory liberality. The surgeon who had to leave town left fifty pounds as his contribution to the general fund: Sir William Gull left three.

These minor details of professional life will perhaps interest you more than the mere narrative of the public proceedings, which you will find fully recorded in the medical papers, and especially, of course, in the journal of the Association. No doubt also some of your own countrymen will record their independent impressions of what they saw on the surface. What I write will perhaps help your readers to understand the sources and character of the influence and activity of this Association, which has not at present, so far as I know, any rival among professional associations, in the extent, power, and completeness of its organization.

The late meeting was not remarkable for the excellence of the addresses. The only articles which were

noteworthy were those of Professor Parkes of Netley, on Medicine, and of Professor Sanderson, on Physiology. Both were reviews of progress which were everyway worthy of the occasion, and of which you may perhaps think it worth while to transfer parts to your columns. The address on Surgery, by Mr. Wood, is perhaps the weakest ever delivered before the Association. It is ill written, weakly conceived, and only half informed on such subjects as antisepticity in surgery, and the use of pneumatic aspiration, with which it deals. Oddly enough, it speaks of the pneumatic aspiration of strangulated hernia, a proceeding of quite a commonplace character and which is at least entirely innocuous, as one of unparalleled audacity, such that the writer could not nerve himself to its contemplation. A perusal of the chapter on aspiration of strangulated hernia in Dr. Dieulafoy's most interesting newly-published monograph ("A Treatise on Pneumatic Aspiration, a New Medico-Chirurgical Method of Treatment and Diagnosis in Hydatid Cysts and Abscess of the Liver, Pleurisy, Empyema, Hydarthrosis, Strangulated Hernia, etc." By G. Dieulafoy, M.D. Smith, Elder & Co., London) would certainly greatly modify that fear of Mr. Wood. Altogether, the address was below mediocrity, and was much to be regretted. There are, however, extenuating circumstances which must modify foreign criticism. Mr. Wood stands only in the third place among our London surgeons, and his name figured only accidentally on the list. It was intended and arranged that Mr. John Erichsen should give the address, and, failing him, Mr. Prescott Hewitt. Mr. Erichsen had accepted the task; but about a month before the time came for fulfilling it, his health gave way under the effects of a wound received in removing a cancerous tongue, which had brought on a state of chronic pyæmia. Mr. Prescott Hewitt was unable at short notice to accept the task, and by an odd sort of chance the next refusal fell to Mr. Wood, whose name had been put on the list accidentally and at the suggestion of a zealous friend willing to pay him what seemed at the time a nominal compliment. Mr. Wood had not much time to prepare his address, and it need not be judged harshly: we must only ask you not to take it as a specimen of what should be offered as a review of surgical progress by a representative metropolitan surgeon. Two other gentlemen would, it is stated, have gladly accepted the office, from whom we should have had a very different sort of oration,—Sir Henry Thompson and Mr. Spencer Wells.

The meeting had the advantage of the presence of some eminent foreigners; among them Professor Virchow and Baron Langenbeck, Professor Bardeleben, Oscar Liebreich, Binz of Bonn, Busch of Heidelberg, Lazarewitch of Kieff, Noël Gueneau de Mussy of Paris, Ollier and Chauveau of Lyons, Gosselin, Marly, Moreau, Spiegelburg, Cornil, Dieulafoy, and many others. Some eminent Americans were here from other cities than yours, including F. Barker and Bumstead of New York, and the delegates of the American Medical Association.

As to the uses of such a meeting, its first use is no doubt the great social use of union, greeting, affirmation of fraternity, of the common pursuit of large objects, of the acceptance of strict ethical principles, and the attachment to the pursuit of the sciences, and the attainment of the objects declared in the speeches and resolutions. The more important parts of the business are the reception of the addresses and reports, and the re-election of the committees which I have described, and then the sectional meetings. A great mass of scientific papers was read; but of these more may be said at another time. The speeches, the resolutions in favor of sanitary reform, of army medical reform, of poor-law medical reform, and the renewal of the organization of the Association for the year, attracted a very great amount of public attention. The *Times* gave every day four columns of its space to the reports; the Premier, Mr. Gladstone, attended the dinner, and paid public homage to the higher aims and more elevated functions of medical bodies to which this meeting testified; and, almost for the first time, the medical profession appeared as united in one powerful body for great objects of no selfish character, but indissolubly joined with good government and human progress. Hence this meeting has been a great success, not only for the Association, but for the profession at large. This is acknowledged by all the medical journals; but, inasmuch as the extension of the Association is necessarily coincident with a diminution in their circulation and influence, and every subscriber gained for the Association is one taken from the *Lancet* or the *Medical Times*, the warmth of their applause is a good deal tempered by financial considerations; and they are especially of opinion that it is preposterous for an association of medical men to own their own medical paper and to manage to carry on their association and publish their paper together for a total subscription of twenty-one shillings a year, while the subscription to the other papers alone is thirty shillings a year. Hence they advocate the diversion of the funds to any other purposes than those which have this year won a further accession of a thousand subscribers,—especially to a benevolent fund or to scientific grants. The advice has been annually tendered for a good many years; and the Association has thriven so well by not accepting it that it is a little surprising it should be so constantly repeated.

To the Editor of the Philadelphia Medical Times:

SIR,—I happened to be in the town of Washington, Pa., a few weeks ago, when the telegraph announced the finding of the body of Thomas Munce in the vats of the University of Pennsylvania, and I could not but heartily sympathize with the storm of excitement and indignation it aroused. Look at the facts. Thomas Munce was a well-known, highly respectable, elderly, bachelor farmer of Washington county; a man of means, worth from $75,000 to $100,000; of somewhat impaired intellect (result of an injury to the head sus-

tained some years ago), and erratic as to his times and ways. He left home unexpectedly, and was last seen on the 2d of July or early on the 3d at the Union depot, Pittsburgh. Later on the same day, whether as the result of accident, design, or of his own motion, his dead body is found in the Schuylkill and taken to the Morgue. *In less than forty-eight hours* from the time of his arrival in this city he is—minus watch, spectacles, and money—within the walls of the University of Pennsylvania, *injected*, and, with other victims, consigned to the vats to await the coming "lecture season" with its hungry "clubs of five." His spectacles fall a prey to one; his watch to another,—the driver of the coroner's wagon, who, after the excitement has somewhat died away, "spouts it" at the pawnbroker's shop, and thus a clue is given, which, followed up, ends with the body in the University vats and the driver under arrest. Well for Munce and his family that he journeyed eastward in the summer-time: a little later in the season, and, despite the friendly watch in the pawnbroker's shop, the "deep damnation of his taking off" would have remained a mystery till "the crack of doom." With the legal investigation now going on we have here nothing to do. 'Tis true, the coroner gets his eight dollars for burial (which our learned District Attorney endorses as proper and right, for the coroner's horse must be fed, whether the man be buried or not). 'Tis true, the superintendent of the city burial-grounds buries him,—*on paper*,—and gives his certificate to that effect. 'Tis true, the tax-payers pay the burial-fees and for the coffins,—the same old coffins which, a professional tells me, "have done this sad service and been sold over and over again to the city for many, many years." 'Tis true that the whole scandalous farce is a burning, blistering disgrace to our city; but we leave that to the law. Professionally, are our own skirts clean? A few years ago, when by the earnest efforts of our medical brethren (and especially the College of Physicians) the appropriation of unclaimed bodies for scientific purposes was legalized, and "body-snatching" became a thing of the ghostly past, society rejoiced, and the profession felt that a great advance had been made in the cause of science and humanity. But, sir, the indecent haste with which "a poor unfortunate" is swept out of sight, even for *scientific* purposes, shocks our moral sense. This corono-janito-medico combination savors too strongly of the "snap judgment" "sharp practice" order to suit our average citizen. The whole story, apologize as they may, is pitiful and disgusting and disgraceful to the last degree, and demands a radical correction. Let the bodies be *embalmed*, as Dr. Hodge calls it (injected with chloride of zinc—15 gr. to ℥j is the usual way; simple, cheap, and durable), by the coroner's physician, and kept in some convenient place a proper time for recognition. Then, with honest officials, we may hope that another such chapter in the history of our city will never be written, and elderly country gentlemen will not hesitate to visit us and accept the hospitalities of the City of Brotherly Love.

R.

REVIEWS AND BOOK NOTICES.

A PRACTICAL MANUAL OF THE DISEASES OF CHILDREN: WITH A FORMULARY. By ED. ELLIS, M.D., etc.

This book aspires to the name and uses of a manual. To produce a really good manual is certainly not easy. To be concise, accurate, and bright,—to tell the story of disease and remedy clearly and sharply, that the book may be hastily read yet quickly understood,—graphically and forcibly, that it may be long remembered,—these are some of the aims of a good manual. We have no wish to find fault, yet might suppose that cerebro-spinal meningitis had been known long enough to merit mention. We also were taught, and still believe, the typical duration of typhus fever to be fourteen, and of typhoid fever about twenty-one, days,—the author placing it at twenty-one and twenty-eight respectively. By a typographical error, p. 84, the well-merited claims of Dr. Sansom in connection with the sulphocarbolates are ignored, and credit is given to a Dr. Sansum, with whose name we are not familiar.

The student of physic, like the student of metaphysics, must paddle wearily through many a stagnant swamp of exploded error before he emerges into the swift-running stream of present truth. Why students are not told at once what is the accepted doctrine of the present, and allowed to grub into the past at their own option and inclination, we could never understand. Certainly by this method our overburdened course of study would be wonderfully relieved. This digression simply means that the manual under consideration is in some respects antiquated, and not always correct.

The author's chapter on typhoid fever states, as mentioned above, its duration at twenty-eight or thirty days. Especially in the case of children this seems a curious error; for in them so often is the first week completely overlooked that the fever has an apparent duration of only fourteen. In diet, "beef-tea, veal-tea, light pudding without currants, and milk" are recommended. "And the last shall be first." We believe that animal broths nearly always aggravate the diarrhœa, and in mild cases cause it; and that any one firmly withholding them during the fever, and depending on milk alone, will, after a few trials, be convinced. Especially would we warn against the—fortunately, in this country almost unknown—abomination, veal-tea.

On p. 93, "it must be remembered that children do not bear narcotics well." They bear them better than stupid medicators think, who, not knowing how much they require, over-dose them, and then make the above hackneyed remark. By narcotics we presume opium is meant. Surely no one will say that children are particularly susceptible to belladonna as a rule.

Page 92, "the abdomen may be covered with a moist, warm cloth well sprinkled with turpentine, or a bran poultice." The innocent and not too experienced student who should suppose the two synonymous would ere long discover his mistake: they are not equally calculated to remain upon the abdomen.

The mainstay and sheet-anchor also is noticeable. Witness the author's almost comical description (p. 115) of what to do with a child who has fits. Perhaps it has eaten something improper. What has it had? "A good purgative," he triumphantly exclaims, "will cure it. Calomel and sugar is the best, as it can be put on the back of the tongue and sucked down without difficulty." If all things which can be so placed and so disposed of are good purgatives, what a wide and popular range of drugs is opened to us! A little further we read, "for inward fits calomel will be required at once," conveying the impression to the above-mentioned unskilful student that without calomel "inward fits" are doomed to a rapid and early destruction.

With the exceptions noted, the manual suits us. It is pleasantly written, well printed, and ends with a formulary of drugs, from which we think the average American reader, if he try, can scarcely fail to gain some useful hints in prescribing.

SYPHILIS OF THE SKIN AND THE ADJACENT* MUCOUS MEMBRANES. By DR. MORIZ KAPOSI, Lecturer in the University of Vienna. With Chromo-lithographic plates executed by Dr. CARL HEITZMANN. In Three Parts. Part I., with Twenty Plates and Four Woodcuts. Vienna, 1873, William Braumüller.*

We have before us the above work, which has just appeared from the hands of its well-known authors, Drs. Kaposi and Heitzmann. Although only the first part of the treatise, it alone forms a valuable contribution to the study of syphilis. The volume, a large and handsomely executed specimen of the publisher's work, consists of concisely written chapters upon the soft and hard chancre and bubo. The text is elegantly illustrated by a large number of finely drawn and colored plates from the hands of Dr. Heitzmann. It is a volume of rare excellence and merit, portraying the skin-lesions of syphilis with unusual precision and truthfulness. We welcome its appearance as one of the most important publications of the year, and wish for it a wide-spread circulation.

HANDBOOK FOR MIDWIVES. By HENRY FLY SMITH.

We can speak only in praise of this little work. Though designed for educating a class of women as skilled midwives to take entire charge of easy cases and recognize difficulties in time to summon more intelligent assistance, it is superior to most works of the kind for students, especially for those intrusted with cases of midwifery, as often occurs very early in their studies. The exceedingly difficult task of explaining technicalities clearly to those without previous education on the subject is admirably done. We are astonished at the clearness and correctness of the book, which is small, beautifully printed, and well illustrated. There are no clap-trap pictures.

GLEANINGS FROM OUR EXCHANGES.

PSORIASIS—ITS ETIOLOGY, RELATION TO RHEUMATIC DISEASES, AND THE RATIONALE OF A COGNATE TREATMENT (by F. Le Roy Satterlee, M.D., Ph.D.).—The want of success attending the treatment of psoriasis by any of the received methods has given rise to a sense of impotency and dissatisfaction which has suggested a search for the cause of this disease. An identity or similarity of cause in psoriasis and certain rheumatic affections has occurred to Dr. Bence Jones and been hinted at by two or three other practitioners, but nothing has been presented showing any extended testing or following up of the suggestion. While studying this affection of the skin, both in private practice and also in the service of the New York Dispensary for Diseases of the Skin, it fell also to the lot of Dr. Satterlee to treat many rheumatic cases. The success of the latest treatment of rheumatism confirming the theory of its cause, and the observation of cases of psoriasis suggesting similar chemical actions, an inquiry of patients with the skin-affection developed almost universally the precedence or concomitance of rheumatic affections or at least a rheumatic diathesis in the individual or family, and the same characteristics in inheritance of tendency, persistency of continuance, or recurrence, in both diseases. Some two years ago he began to test the similarity of physical conditions present in the two diseases under consideration, and to treat psoriasis on the theory of an identity of the materies morbi. The results were so uniform and permanent that he feels warranted in presenting a representative case which had withstood the ordinary forms of treatment administered by the most competent men, and then the rationale and argument for the view advocated by himself.

P. H., aged 24; Irish; by occupation a porter; had suffered from psoriasis for eleven years. The disease spread rapidly until the whole body, the head and hands alone excepted, was covered; the spots, of the size of an English shilling, were always dry and scaly and were close together, the patient always worse in cold and damp weather. After five years the hands and face were also involved. The patient's father was killed, and nothing was known of his family history; the mother died of some disease of the bladder (probably calculus); several of his brothers and sisters had a similar eruption. The patient's habits had been good; he had always worked hard and led an active life; had suffered from rheumatism especially within later years. Seven years ago he was treated internally at Manchester, England, with no effect; in this country he had tried the homœopathic and hydropathic treatments, but with no effect except the washing off of the scales by excessive bathing; afterwards he received treatment by Fowler's solution, sapo viridis, alkaline baths, for four months, with but slight effect upon the affection, and he was discharged at the end of this time as incurable. At this time he suffered for two weeks from inflammatory rheumatism. After again trying homœopathic treatment for a short time, he was sent to the Dispensary, and came under the charge of Dr. Satterlee, by whom he was treated on the theory of the presence of an excess of uric acid requiring oxidation up to the point of urea. He was treated by alkalies internally, the diet being restricted to vegetables and fruits and vegetable acids, meat being forbidden, and no external treatment used except an occasional alkaline bath. In three weeks the result manifested itself, and the eruption gradually cleared off, until at the end of three months he was completely well, having gained several pounds in weight during the treatment.

There are two conditions which are the most likely to be the cause of a disturbance in the balance of the nutritive process essential to health. First, a given constituent of the food in too great an excess, and conditions retarding the normal changes of tissue, may prevent the appropriation of new material to construct healthy blood. Thus gout and rheumatism and allied affections are found in those of sedentary habits addicted to an over-indulgence in nitrogenous diet and generous wines. From these causes arises an excess of fibrin in the blood, and from this combined with conditions retarding the transformation of effete tissue there results an incomplete oxidation of the proteins of the body, intermediate compounds are formed, and these constitute the materies morbi of certain diseases, *e.g.*, rheumatism, etc. Second, the opposite state of affairs is found in the pyrexiæ, in which there is an excessive excretion of nitrogenous compounds from the body, and in the treatment of which such agents are employed as counteract oxidation. Another demonstration of these two opposite states Dr. Satterlee finds in the fact that in his observations he has never found rheumatism or psoriasis in the same subject with consumption.

If, then, these two diseases are looked upon as due to the same general cause or condition of system, the result of the metamorphosis of an excess of nitrogenous

* Die Syphilis der Haut und der angrenzenden Schleimhaüte. Von Dr. Moriz Kaposi, Docent an der Universität in Wien. Mit Taflen in Chromolithographie ausgeführt von Dr. Carl Heitzmann. In drei Lieferungen. I. Lieferung, mit 20 Taflen und 4 Holzschnitten. Wien, 1873, Wilhelm Braumüller.

substances, the treatment readily suggests itself. The diet must be restricted, so that the amount of nitrogenous matter taken into the body may be diminished, and such remedies must be administered as tend to promote oxidation, so that the excess of nitrogenous matter may be oxidized up to a point at which it becomes capable of being readily eliminated from the body. This is accomplished most readily by the alkaline salts; the vegetable acids also, which are converted into carbonates for this purpose, have the same action. The alkalies do not act by neutralizing the uric acid, as was at first supposed, but they prevent its formation in excess by oxidizing it up to urea. In this treatment of psoriasis, two or three weeks sometimes pass before any good effect is noticed; then the eruption begins to pale, the formation of scales is checked, and the patient finds himself in an improved general condition, feeling better and stronger than he has done since the appearance of the disease. The spots vanish by fading first at the centre, forming rings which break up, leaving pinkish stains which finally yield. With the entire disappearance of the eruption the patient finds his general health much improved: he has frequently gained weight during the treatment. The vegetable diet has been after a cure maintained to some extent, but not so stringently as during the treatment. If during the treatment a meat diet and the use of alcohol is permitted, the disease is found to retrograde in its progress towards cure. As psoriasis is essentially a chronic affection, a prolonged treatment, sometimes extending over six months, may be required to attain the desired result.—*New York Medical Journal.*

The Use of Digitalis in Maniacal Excitement (by W. Julius Mickle, M.D., Medical Superintendent Grove Hall Asylum, Bow).—The use of digitalis in various forms of insanity has been advocated by various writers, but there is still a great difference in opinion as to its efficacy, as to the appropriate method of administration, and as to the size of the dose, the same preparation being given by different physicians in doses ranging from ten minims up to half an ounce. In none of the cases treated by digitalis were other means of treatment neglected; the general treatment was the same adopted in other cases suffering from similar attacks; out-door exercise and full diet were freely allowed, and means employed to avoid irritation and to distract the mind from morbid objects of attention. In a majority of cases the use of the drug had but little reference to their cure, but was employed for the mitigation of distressing, exhausting, or dangerous symptoms of chronic and often incurable affections. The preparation usually was the tinct. digitalis (B. P.), and the average dose was thirty minims three times a day. Many of the cases thus treated were those of chronic mania in which there occurred exacerbations of excitement, in which the patients became agitated, noisy, and violent, enraged by delusions and vivid hallucinations.

The benefit derived from the digitalis, as well as the length of time during which the administration was continued, varied greatly in different cases. In the case of maniacs in whom the paroxysmal excitement recurred at short intervals, the administration was often prolonged; in those in whom the recurrence was at longer intervals, there was no reason for prolonging the use of the drug after the cessation of the paroxysm. In others of the cases subjected to this treatment, the excitement was more diffused and uniform, the exacerbations being very moderate in degree, thus offering a contrast to the patients of the first-mentioned class. The symptoms of excitement arising in the course of general paralysis were also treated with the tincture of digitalis in the same doses.

Some of the cases are excluded from the tabulated report, owing to incompleteness of the records of the cases; but there remains a list of forty-one patients to whom this treatment was applied on sixty-six separate occasions, of whose cases full records have been kept. Out of these forty-one patients twenty-five are recorded as cases of chronic mania, and the digitalis treatment was made use of forty-four times. These twenty-five cases can be subdivided into two classes: 1, those cases in which the excitement was paroxysmal, and 2, those in which the excitement was subcontinuous or continuous. In tabulating the results of this treatment in these two classes it is seen that there is a marked difference; those patients suffering from chronic mania with paroxysmal excitement having been benefited in a much more marked degree than those belonging to the other class. Various forms of maniacal excitement in general paralytics were also alleviated, and acute or subacute mania, and chronic mania with nearly continual excitement, were usually moderated thereby. In some cases in which digitalis had been used for a time and then omitted, it was noticed that the later course of the affection was milder, as if the period of quietude enforced by the drug had permitted a recuperation of the nervous power. The effect of the administration of digitalis upon the pulse was also carefully studied and recorded, and it was found that in those cases in which the drug had the effect of calming the excitement the high pulse attending the paroxysm was also brought down. In one case the pulse sank from one hundred and thirty-five to ninety on three successive days upon which the use of digitalis was pushed. In subcontinuous maniacal excitement the pulse is occasionally very high, usually moderately high, and not unfrequently low; but, whatever the frequency was, it was found that the usual tendency of digitalis was to reduce it; but still it was not found that the pulse was invariably retarded in every case.

Dr. Mickle considers from his observations that in the cases benefited by digitalis the maniacal symptoms were associated with disorder of the cerebral circulation, and that the drug exercised its beneficial action either by giving time to the heart's action, thus enabling it to overcome the tendency to local congestion, or by acting more directly on the peripheral arterioles, and thus immediately influencing the cerebral circulation. In a few cases in which no calmative influence was noticed until foxglove had been given till vomiting had been induced, the pulse was as a rule much diminished in frequency; but in some patients in whom during excitement the pulse rose very high, it was lowered but slightly even when emesis came on. In every case in which vomiting was caused, the excitement was diminished; but in some of the cases the effect was of but temporary duration. In most of the patients no gastric disturbance occurred; several even gained considerably in weight while under treatment. Comparatively small doses were found to exert an effect different from that of larger ones, and to produce or tend to a calmative and tonic influence in both cerebral and cardial agitation. Any unpleasant gastric symptom was interpreted as a sign that beneficial effect was being replaced by detrimental action, and that total or partial omission of the treatment was authorized. Any marked alteration of cardiac rhythm or sounds supervening while digitalis was being taken was felt to justify immediate cessation of its use; but cardiac contra-indications were extremely rare.—*Journal of Mental Sciences*, July, 1873.

Chloral in Pertussis (by P. Brynberg Porter, M.D.: *New York Med. Journal.*)—In a former paper, Dr. Porter stated that the administration of this drug had not failed in a single case of hooping-cough to produce some alleviation of the symptoms. Since the publication of his former article, he has used chloral

very extensively in this affection, and, though deeming it a most efficient remedy in a majority of cases, has found that it does not accomplish quite all that he anticipated from it. Possibly this may be due to a difference in the type of the epidemic, which according to his observation has been of much greater severity than that of last year. He has not lost a case while pursuing chloral treatment; and even those cases which seemed little affected by the drug may have been to some extent held in check by its administration.

The Solvent Action of the Papaya Juice on the Nitrogenous Articles of Food.—Assistant-Surgeon Gopal Chunder Roy has written an interesting paper on this subject in the *Calcutta Journal of Medicine*. The power of the papaya-tree and its juice to render meat tender is a popular belief in India. Dr. Roy's experiments confirm the truth of it. They were conducted at Netley under Dr. Parkes's notice, and are detailed at length in the paper referred to. The juice, or a solution of it, undoubtedly softens, digests, or dissolves meat, albumen, and gluten. Dr. Roy compares the action to that of a ferment, and suggests the administration of a few grains of the dried juice after meals in cases of indigestion depending on a deficient secretion of gastric juice.—*Indian Medical Gazette.*

MISCELLANY.

A Triumph of Art.—Boston stands pre-eminent in the production of exquisite and wonderful optical instruments. Mr. Tolles has just achieved the great result of producing a $\frac{1}{75}$ objective for microscopic uses, a glass of such difficult construction that we believe no optician has ever attempted it before. The power of this objective is such that a *single white blood-corpuscle covers the entire field of vision.* Mr. Tolles has produced two of the finest $\frac{1}{50}$ objectives ever constructed, one of which is in this city, the other is in the hands of a Western gentleman. The angular aperture of one is 120°; that of the other, and the last constructed, is 165°.

These objectives are of great excellence, and, in the opinion of competent microscopists, far surpass in defining power and clearness of field those of European make.—*Boston Journal of Chemistry.*

Pregnancy in the Aged.—Dr. Meynert has communicated to us the following case which has fallen under his own observation. A lady died at the age of eighty-five, having had four accouchements. The first took place at the age of forty, the second at forty-eight, the third at fifty-one, and the fourth at fifty-six. Five girls were born, of whom three are still living, the two twins being seventy-seven years old, and the youngest child seventy-one. These three persons, the two eldest of whom have been married and have several children, still enjoy the most excellent health.—*Lyon Médicale.*

A Monstrous Blunder.—A comical story comes from Paris, the authority being a correspondent of the *Pall-Mall Gazette.* The Shah of Persia, when in Paris, went to the Jardin des Plantes, and was very much pleased with what he saw there, and with the courtesy of the directors; so much so, indeed, that he made notes of the names of the men of science, with the view of "remembering" them, in the sense in which people who hope to get something ask to be "remembered." The other day his Majesty's compliments arrived, in the shape of "lions" and "suns," and other "orders," which count for a good deal in Persia. Unhappily, the Persian monarch somewhat dashed the pleasure of the "decorated" men of science by an awkward accident. He had noted down the names of MM. Geoffroy St.-Hilaire, Milne-Edwards, and other savants; but in company with them he had also written the names of some of the "extinct animals" whose relics are preserved in the museum; and, unluckily, the two sets of names got mixed up together. So it happened that when the men of science received Persian decorations, so also did the megatherium, the dinotherium, and other "fearful wild fowl" of the same character.

Contributions to a Scalp.—A young lady who had her scalp torn off by an accident in New Haven recently is reported to be doing finely. The *Journal and Courier* says, "The physicians have found thirteen persons willing to part with a small piece of their cuticle, and the medical gentlemen have placed the contributions on the head of the patient with gratifying results. As one after another volunteers to let the doctors clip off a piece of skin, the number of those willing to do likewise increases, and it looks as if the girl would have a scalp and a head of hair again. The younger physician attending first set the laudable example."

A recent homœopathic writer gives two hundred and eight symptoms as furnishing separate indications for treatment in cerebro-spinal meningitis; and for each of these symptoms he enumerates from one to nine appropriate remedies (*similima*).—*North-Western Medical and Surgical Journal.*

The Italian Senate has adopted the article of the new sanitary regulations which accords a pension to families of physicians who have fallen in the performance of their duties during the prevalence of epidemics.—*Lyon Médicale*, June 22, 1873.—*Clinic.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM SEPTEMBER 2, 1873, TO SEPTEMBER 8, 1873, INCLUSIVE.

Kimball, J. P., Assistant-Surgeon.—After completion of duty assigned him in Department S. O. 190, c. s., to report in person at these Headquarters for further orders. S. O. 189, Department of Dakota, August 25, 1873.

Yeomans, A. A., Assistant-Surgeon.—Ordered to Washington, D.C. S. O. 178, A.G.O., September 6, 1873.

PHILADELPHIA MEDICAL TIMES.

SATURDAY, SEPTEMBER 20, 1873.

ORIGINAL COMMUNICATIONS.

TWO CASES OF FISTULOUS TRACTS CLOSED BY THE USE OF CARBOLIC ACID.

BY H. G. LANDIS, M.D.,

Niles, O.

I GIVE the cases in full, to show the origin of the fistula in each, and that the reader may judge of the efficacy of the acid.

Case I.—Mc—, æt. 64; has had hydrocele for a number of years; has been tapped several times; is of a very nervous temperament, and has had financial misfortunes recently, which greatly depress him, and make him unfit for any severe operation. The hydrocele is on the right side, large, and increasing in size, and is now so annoying that he desires to be tapped. Desiring to avoid the use of chloroform, on which he insisted (greatly dreading the pain which the former tappings had given him), I tapped it in this manner:

January 25, 8 P.M.—The needle trocar of a hypodermic syringe was passed into the tumor, having attached to it two inches of rubber tubing. In the other end of the tubing a two-ounce syringe was introduced, and by slowly moving the piston was readily filled. It was then emptied and reapplied, and in this way a pint and a half of fluid was withdrawn in thirty-five minutes. A somewhat tedious process, but one absolutely devoid of pain and inconvenience to the patient, and to be recommended in cases where the patient is extremely nervous.

January 26.—Feeling none of the inconvenience that the usual method of operating had always given, he had coition before arising, and then engaged in hard labor. By 1 P.M. there was a slight scrotal swelling, and a little fever, which steadily but gradually increased until the next day, when the affected side of the scrotum was as hard as a board, and considerable pain was felt in the right testicle. As the inflammation had come, it was determined to make use of it for the purpose of obliterating the sac, and cloths of lead-water and laudanam were applied to keep it in due bounds; three cathartic pills were also given, as he had had no movement of the bowels since the day of operating.

January 28.—Inflammation stationary, but he is in a depressed condition, and expresses great fear of death. No passage. Repeated pills, and gave Seidlitz powder in the morning; ordered injection P.M., which was not given.

January 29.—Bowels tympanitic; pulse rapid; colicky pains. Gave two injections, after which there was a slight passage. The scrotal inflammation is a little less in degree, and after strapping it the pains were relieved. 8 P.M., pulse quick; paroxysms of abdominal pain. Gave chloral, gr. xl, and another injection, which produced a good evacuation.

January 30.—Better. Tightened straps. The inflammation has been rather more severe than necessary, owing to my attention being drawn away to his general condition. The tumor is now of the same size as before tapping.

January 31.—Complains of continual thirst, with dry tongue. This was relieved by a few doses of ol. terebinth. and acid. carbolic., but reappeared every few days for some time.

February 1.—Took off straps and applied a narrow roller bandage fastened to a belt around abdomen. By this contrivance the compression was made more effective, and the size of the tumor diminished somewhat. For the next week he had symptoms of the formation of pus. Pulse 90 A.M., 100 P.M. Slight hectic fever, and a tongue kept moist only by the means already alluded to. The depression of spirits was also continued.

February 18.—Having made no headway by compression, and finding the reaccumulation of fluid evident, tapped in the same manner as before, and drew off about a pint of fluid, which was slightly turbid. This was followed by much improvement in his general condition. The swelling was found to be mainly composed of the thickened walls of the scrotum (at least an inch in thickness), and the cord and testicle were also greatly enlarged by deposits of lymph.

On the 23d, the same procedure was attempted, but this time the contents of the sac were almost entirely pus and flakes of lymph. A small incision was made, through which the pus did not flow freely, and the walls were so thick that a sufficiently large opening would have necessitated an external wound of such size as to alarm the patient. A flexible catheter was therefore introduced, and the cavity pumped out. This was subsequently repeated several times, a pledget of muslin being packed in the wound *ad interim*. Tinct. iodine was applied externally, and subsequently an ointment of iodine and belladonna. Under this course the size of the sac and its pus-producing tendency were diminished very gradually, until in March there was only a fistulous tract extending anteriorly from the centre of the right side of the scrotum (the situation of the incision) to the opposite wall of the sac just above the testicle, and apparently the sac-walls had entirely coalesced except along this tract. Occasionally the external wound would heal up for a day or two, and pus would collect, and occasion considerable distress to the patient until the wound was reopened. This existed until the middle of April, when I resolved to syringe out the fistula with a one per cent. solution of carbolic acid. This was done by passing a small flexible catheter to the bottom, and gradually withdrawing it while the solution was forced in by the apparatus detailed above. This was done every other day for a week and a half. At the end of this time it had permanently closed. Three ounces of the solution was the whole amount used. In another month the parts were of normal size. As the fistulous tract had been maintained for over a month without change, I certainly think that the solution was curative in its action.

Case II.—J. S., æt. 21; after exposure was attacked by catarrhal inflammation of the right ear, which was stopped in two or three days by injections of a solution of sulphate of zinc. In a few days he went on a spree, and the otitis reappeared. This time the inflammation was not so tractable, and, becoming a little impatient, he yielded to his friends, and had a large blister applied behind the ear and extending down the neck several inches, by an "eclectic medicine man." Finding that he only gained an additional disease by this move, he applied to me again to heal the blister. When this had been half accomplished, the discharge from the ear diminishing at the same time, he again fell into the clutches of the eclectic, who applied caustic potassa to the neck, two inches below the mastoid process, and burnt out a hole an inch and a half in diameter, and a half-inch deep after the slough was removed. This was followed by diffuse inflammation of the cellular tissue, and burrowing abscesses following the fascia in several directions. In a few days the patient mustered up courage to return to first principles, and with much

bodily remorse, if not mental, requested me to finish the affair. By this time the ear was nearly well, and we had only the eclectic disease to treat. Several fistulous tracts radiated from the wound, of which the longest extended upwards for three and a half inches, passing behind the mastoid process and touching the periosteum of the occipital bone. This was in a week the only one remaining. Poultices, ointments, washes of divers sorts, and probings, were resorted to; as in the first case, it would close externally, pus would collect, and it would reopen. After a month's failure to diminish its size in any way, I resorted to the injection of a one per cent. solution of carbolic acid, passing a very small flexible catheter to the bottom, and attaching a syringe, as in the first case. Four applications were sufficient. In one week from the beginning of this treatment the neck was well.

These tracts will often form after inflammations of cellular tissue, and if the solution here recommended prove as generally successful in the future, it furnishes us with a much more prompt and less painful remedy than we have heretofore possessed.

August 30, 1873.

SUGGESTIONS FOR THE TREATMENT OF THE ALGID STAGE OF CHOLERA.

BY HARVEY L. BYRD, M.D.,

Professor of Diseases of Women and Children in the College of Physicians and Surgeons of Baltimore, Md.

IN view of the fact that cholera exists and has prevailed to a considerable extent in some of the cities and towns of the West and Southwest, and the world-wide knowledge of its great fatality under all the plans of treatment hitherto pursued, we are induced to offer some suggestions for the management of the disease in its most fatal stage.

In the first stage of cholera, experience has fully demonstrated the value of medical treatment when based upon correct principles, and recovery is, generally speaking, satisfactorily frequent. But in the algid stage and stage of collapse death takes place to a lamentable extent, and, so far as the knowledge and experience of the writer go, the prognosis in this stage, under any system of treatment hitherto pursued, is always unfavorable. Fortunately for Baltimore, no case of cholera has been seen within its limits during the present visitation to this country, and it is earnestly hoped that an opportunity may not occur for a practical test of the remedies soon to be mentioned for the treatment of the cold and collapsed stages of the disease, in this city. Though singly they are not new, they are brought to the attention of the profession now that they may be tried in the order indicated below, if deemed advisable or proper by the physicians engaged in the management of the disease where it prevails. In summing up and comparing his past experience and success and the success of the profession generally in the treatment of the stages of the disease alluded to above, the writer feels warranted in making such suggestions in regard to their management as may offer a plausible, not to say philosophical, hope of success. The blood is undoubtedly altered in a most essential manner in all cases of cholera, particularly when the disease has advanced beyond the first stage, and the capillaries, and nerves controlling their action, become involved in the copious escape of its more fluid constituents. The precise character of the change which the blood undergoes in a person exposed to the choleraic poison for a sufficient time to produce the disease we have at present no positive means of ascertaining, and speculations of our own in regard to it would be out of place in a brief paper like this. The altered condition of the blood, and the perverted or abnormal action of the capillaries and the filaments of nerves distributed to them and to the skin and mucous surfaces of the stomach and intestines, are phenomena that may be witnessed in every case of cholera on the occurrence of the algid or collapsed stage of the disease. The remedies proposed in this stage of cholera are transfusion of healthy human blood, or that of sheep or goats, the hypodermic injection of ergot or ergotine, alone or in conjunction with strychnia, and the electro-magnetic current. The action of these agents in the algid stage of cholera must prove beneficial, if we consider their physiological effects on the human organism as fully established. It is not proposed they should be used simultaneously, but probably in something after the following order: First, transfusion of healthy human or sheep's blood in sufficient quantity; then the hypodermic injection of ergotine for its specific action on the capillaries, and in a short time, if necessary to impart tone to the capillary nerve-filaments, the hypodermic use of strychnia; and, lastly, the application of the faradaic or electro-magnetic current to the nerves, as the par vagum, requiring assistance in the performance of their accustomed functions. With this agent—electricity—we have dried and imparted warmth to the preternaturally wet and cold skin, and excited the kidneys to action, in congestive conditions the result of malarial poisoning, and also in a case of cholera during collapses. Vide *Charleston Medical Journal and Review*, vol. viii. p. 628, 1854.

The foregoing suggestions are the result of careful thought and mature deliberation, and will certainly be practically tested should the algid stage of cholera again claim our professional attention. Our experience has shown that *the recumbent position should be rigidly enforced* as soon as the first stage of the disease is passed, and *the use of the bed-pan insisted upon for several days* after the grave symptoms have been subdued. Mechanical pressure of the abdomen and compression of the anus have also proven serviceable under our observation. This is easily effected by compresses of cloth over the intestines and anus, kept in place by a broad T-bandage. With this bandage pressure can be made, and the peristaltic movements of the intestines modified, if not controlled, even when it is absolutely necessary to allow the occasional escape of the contents of the over-distended lower bowels by the temporary removal of the anal compress. The foregoing, with the judicious use of ice internally and externally, and *positive inhibition* of *all* distilled alcoholic liquors, should always claim careful attention, whatever other remedies are used in the algid state or stage of collapse of cholera.

The writer is very positive he has seen *decided*

injury from the use of brandy and whisky in the algid stage of cholera, and cannot recall in his past experience a single instance in which *any* of the distilled preparations of alcohol afforded more than momentary benefit in this condition or stage of the disease.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROFESSOR PANCOAST.

Reported by FRANK WOODBURY, M.D.

TUBERCULOSIS OF THE ANKLE-JOINT.

THIS little girl has inherited disease, and illustrates the influence of a constitutional taint upon the physical development. The life-springs are poisoned at their source, the vital functions performed imperfectly and irregularly, nutrition vitiated, and the whole organism enfeebled. The little subject is thus rendered more susceptible to disease and less able to resist its ravages. Two years of age, her frame is emaciated, the skin is sallow and shows a tendency to eruption, and she has chronic conjunctivitis. She has not the light hair that frequently accompanies these symptoms, which, for convenience, are grouped under the general term of strumous; but this is the case in a large proportion of scrofulous subjects. In France, where scrofula abounds, there is comparatively little light hair; and the negro race, as we know, is quite subject to it. Experience has shown that of the two classes of strumous subjects the brunette is more liable to phthisis pulmonalis than is the blonde, who suffers more from bone- and joint-affections and diseases of the skin.

About four months ago the child's foot was bruised, and this injury has eventuated in chronic disease of the ankle-joint. The inflammation which was then inaugurated has acted as an exciting cause for the deposit of a crude, amorphous material in the soft parts about the bone, and finally in the bone-structure itself. The malleolus appears very much enlarged, and is rapidly progressing towards caries. The disease would end in destruction of the joint if it were not arrested by proper treatment. The patient's bowels are irregular; the breath is offensive, and the tongue furred, with pits on the tongue, showing the orifices of the ducts of the enlarged mucous follicles with the mucus overflowing around them,—a condition which probably indicates that of the mucous membrane throughout the alimentary tract, by which the lacteals are clogged, the digestion is impaired, and the absorption of chyle interfered with. This accumulated secretion in the bowels forms what was designated by the older writers as saburra.

To give the patient the best chance of recovery, we will endeavor to correct the secretions, improve the digestion and appetite, and bring the general health nearer to the normal standard. Until the condition of the alimentary tract is changed, but little benefit can be expected from treatment. We will therefore give, as an alterative cathartic,—

℞ Hydrarg. chlor. mitis, gr. jss;
Sodæ bicarb.,
Pulv. rhei,
Pulv. myristicæ, āā gr. ss.

This is to be given every third night.

As a tonic, she may have the disulphate of quinia:

℞ Quiniæ sulph., gr. xxx;
Acid. sulph. aromat., ℥j;
Tinct. cardamom. comp., ℥j;
Syr. acaciæ, ℥iij. M.

S.—A teaspoonful, in a little water, before meals.

Her diet must be carefully regulated, interdicting pastry, salt meat, uncooked vegetables, candies and all other sweet things, and all food which is digested with difficulty. She may have plenty of eggs, milk, rare beef, or chicken, with a little ale or claret if she likes it. She might be given some weak milk-punch, even, or egg-nog, with positive advantage. As she is anæmic, she may also have a tablet of the pyrophosphate of iron (gr. ij, made up with gum and sugar) after each meal; this chalybeate I prefer, and always use, in these cases, as it is less apt than any other form to blacken the discharges from the bowels and render them irritating.

There is fluid around the joint, and the bone is quite soft. To relieve the tension, and let the fluid escape from its bed, I will puncture in several places, with a delicate tenotome, the different layers of skin, fascia, and periosteum, which are arranged like the alternate elements of a voltaic pile. The bone is so soft that the knife enters it like a piece of soft wood, and stands vibrating, as you see, as if it were stuck into a cedar shingle. Having made ten or fifteen of these little punctures and allowed them to bleed sufficiently, the joint will be wrapped in dilute Goulard's extract and laudanum, and, as far as is practicable, kept at rest in an elevated position. These punctures give the fluids exit, relieve the strangulation, deplete the congested vessels, and do an immense amount of good. Of course, in introducing the knife care must be taken to avoid injuring the larger vessels or nerves. With this precaution I have never seen punctures do harm, and they are a thousand times better than leeching.

In addition to this treatment I will order a wire-splint for the foot and leg, open on one side for the dressing, so as to keep the joint perfectly at rest.

[The case was presented at several successive clinics, and soon was progressing most satisfactorily towards a cure.]

CHEILOPLASTY.

This young man, 20 years of age, is brought by Dr. W. Hartzell from Montgomery County, of this State. Seven years ago he was accidentally ptyalized during convalescence from typhoid fever. This led to caries of the right half of the inframaxillary bone, causing a loss of all the molar teeth of that side of the jaw, and sloughing of the lower lip and part of the cheek. This left an open ulcer, extending under the chin, the borders of which cicatrized very slowly. This loss of substance allows the saliva to constantly dribble on his clothes, obliging him to wear a bandage around the neck and chin. Speech is interfered with, eating is difficult, and he feels incapacitated for business.

The patient is in good health and solicits relief from this troublesome affection. The lower lip on the right side is entirely gone, from just outside the commissure to beyond the median line, and as far down as the junction with the gum.

Cheiloplasty is the name given to the operation for restoring an entire lip or any portion of it, which has been destroyed by accident, the ravages of malignant disease, or other cause. There are many ways of performing a cheiloplastic operation, and they must be selected to meet the peculiar exigencies of the case. The one I shall do to-day is the best one, in my opinion, to remedy a deformity such as we have before us.

In performing this operation it is better not to use an anæsthetic, if possible, as it is done more conveniently with the patient seated in a chair before you, and the risk of vomiting is avoided, which is annoying during the operation. Having the clothing of the patient covered, and his arms held by an assistant, I take a bistoury and refresh the edges of the cicatricial margin throughout its whole length down to the chin, saving as much of the vermilion mucous border of the old lip

as possible. Two incisions, about three-quarters of an inch apart, are then made on each side outward from the chin, but nearly parallel with the jaw-bone. The upper one starts from the commissure, and involves the whole thickness of the cheek; the second goes down to the jaw-bone. The flaps are then freely detached from the bone with the knife, squared at their ends, and brought together in the middle line by the interrupted and hare-lip sutures. The small part of the lip which was uninjured is thus made to form a part of the flap. The flaps must come together without tension, for fear the stitches will pull out. In order to avoid this they must be loosened well back, when they will readily stretch and rest without tension. After tying the spouting vessels, the capillary oozing should be stopped, not by a styptic that destroys tissue, like Monsel's solution or any of the mineral acids, which would interfere with union, but by the soap styptic, which is quite sufficient and rather facilitates union by first intention.

To support the parts and keep them in contact, we place adhesive strips between the sutures, and over all a lint compress spread with benzoated oxide of zinc ointment. He must keep the lower jaw at rest, and feed from the spout of a teapot.

(One week later.)—The union is now complete, and the pins and sutures may be removed, but the parts should still be supported by strips, and the patient must avoid laughing or talking, for the cicatrix is recent and might yet give way. We will permit the flaps to attach themselves to the gum wherever they will, in order to gain as much nourishment as possible. When the cure is completed we can give him ether and divide the attachments to the lower jaw, so as to render the lip movable.

(Twenty-fifth day.)—The patient presents himself with the lip completely restored, and wishes to have it freed from the gum and jaw. Having done this, we insert an oiled compress between the raw surfaces, to prevent their reunion. The muscles about the commissures, part of which went into the structure of the new lip, will gradually pull the mouth into proper shape.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. F. F. MAURY.

Reported by Dr. J. Wm. White, Resident Physician.

FOUR CASES OF EXCISION OF THE HIP-JOINT.

(Concluded from page 789.)

CASE III.—McK., æt. 23, a druggist, and a native of Philadelphia, was admitted to the Philadelphia Hospital on April 16, 1872, with extensive disease of the right hip-joint, in the neighborhood of which there were eight sinuses. One, opening at the femoro-scrotal junction, was directed upward, backward, and outward beneath the femoral vessels, and extended to the iliac bone; another was about four inches below the great trochanter. Three, leading towards the acetabulum, were around the anterior superior spinous process of the ilium, and three more were irregularly arranged over the trochanteric prominence.

From each of them a scanty but offensive discharge constantly escaped. On manipulation of the limb, which was withered and shrunken, there was rocking of the pelvis, but no movement of the articulation, the joint being firmly anchylosed. Complete talipes equinus existed, with shortening to the extent of four and a half inches. The man was pale, thin, and anæmic, although he had undergone a preparatory course of tonic treatment.

Operation.—On April 17, Dr. Maury brought him into the clinic before an unusually large class, and, while chloroform was being administered, explained the circumstances of the case. He then made an incision six inches in length over the great trochanter, carrying it down to the bone and obliterating three of the sinuses. The head of the femur was found separated from its neck and firmly lodged by bony anchylosis in the acetabular cavity, and the femur itself was dislocated backward on to the ilium and strongly united to that bone. There were extensive caries and necrosis of the neck, the trochanter major, and portions of the ilium.

The femur was with great difficulty separated from its attachments, the periosteum, where present, stripped from the bone, the latter sawn in two just below the trochanter, and the diseased structures removed.

The loss of blood was very slight, no ligatures or hæmostatics being required. The cut edges were approximated by four interrupted sutures with adhesive plaster, and oakum was placed over the wound.

Throughout the operation the chloroform was well borne, the pulse keeping strong and regular, and there were no indications of shock or of marked depression. Whisky and morphia were given on recovery from the anæsthetic. For the first twenty-four hours the patient was permitted to assume any position which seemed desirable to him, but was afterwards instructed to lie on his back, with the limb as nearly extended as possible.

April 18.—Pulse 100; slight nausea, relieved by ice and paregoric; no appetite; some pain in the hip and knee.

April 19.—Condition improving; the patient was somewhat annoyed by twitching of the muscles of the leg and thigh, but found relief from the careful application of a bandage. Wound looked healthy, and was dressed with an ointment of the oxide of zinc, adhesive plaster, and oakum,—the latter changed twice daily; urine somewhat scanty, and high-colored, with a copious lateritious deposit. Quinia and muriated tincture of iron were given, and were ordered to be continued.

April 20.—Pulse 100, strong and regular; his appetite was increasing, and the discharge from the wound—heretofore very profuse and sero-sanguinolent in character—was less abundant and more purulent.

April 24.—A free evacuation of the bowels was produced by an enema of warm water. The stitches were removed, and it was found that union had taken place to the extent of one and a half inches at either extremity of the wound, which was granulating in the centre, but remained sufficiently patulous to permit the ready escape of pus. The odor was slightly fetid; but this was corrected by the addition of a little carbolic acid to the oakum. A spasmodic retention of urine necessitated catheterization.

The patient was taking beef-tea, eggs, milk, and the most nourishing diet, with six bottles of porter daily.

April 25.—A small bed-sore appeared over the sacrum, and was dusted with powdered bismuth.

April 28.—Extension was applied to the limb by means of adhesive strips, one brick being used. The discharge from the incision and the sinuses was tenacious, grayish, and free from offensive odor; the wound was granulating nicely, the appetite improving, and the general condition excellent.

May 20.—Since the last date the patient had kept on his back with extension applied; the wound had cicatrized over the larger portion of its extent, but the sinuses remained open, with an increased amount of discharge from those on the inner aspect of the thigh, probably due to the partial closure of the incision.

There was occasional pain in the hip, but none about the knee; a small superficial abscess had formed along the femoro-scrotal junction, and had burst, leaving a fistulous opening. The knee and foot showed, as usual,

a tendency to become inverted, to correct which a small sand-bag was placed along the outer side of the leg and the knee fastened to it by adhesive strips.

Convalescence in this case was somewhat protracted, but in four months the patient was able to walk with slight difficulty. His health was improved after the operation, but he died some time after, of Bright's disease of the kidneys.

Case IV.—R. T., æt. 8, was admitted to the Children's Asylum, August 26, 1872. He had fallen from a wagon some months previously, severely injuring his right hip. Anchylosis had resulted, with the formation of several sinuses in the vicinity of the joint, which became entirely useless. In November, 1872, Dr. Maury operated for his relief, removing the head and neck of the femur, and a portion of the shaft.

He bore the operation well, but his recovery was slow and tedious. An extensive inguinal abscess formed, burst, and is still discharging, together with several sinuses.

The boy is, however, greatly improved in general health, has no pain, and by the aid of crutches walks without any difficulty.

RAILROAD FRACTURES—AMPUTATION.

Operated upon and reported by

DR. JULIO J. LAMADRID,

Middletown, New York.

CASE I.—Charles L., æt. 30, and a brakeman on the Erie Railroad, of strong, healthy constitution, was run over on the 13th of March, 1872. The wheels had passed sideways along and over the right leg, lacerating its tissues, and producing a comminuted fracture of all the bones of the leg. On examination I found that amputation was required. I removed the limb on its upper third. We were unable to apply the tourniquet, for want of room, therefore had to rely upon manual compression of the femoral artery. The hemorrhage was trifling.

Thirty-six hours after the operation the patient had rallied from the shock. Five weeks afterwards the wound had almost healed up, when the patient was taken to St. Vincent Hospital, Jersey City, and returned two weeks after, well and sound.

Case II.—John W., æt. 24, German, and a brewer by trade, was run over by the cars on the 18th of June, 1872, while intoxicated. On examination I found that the wheels had passed over his legs, producing a compound comminuted fracture, and removed both legs successfully by the common double-flap method.

The patient recovered nicely from the shock and operation, and one of his legs healed up by first intention, and the other by granulation. He was able to go out on crutches six weeks after the operation, and in three weeks more was entirely well.

EFFECT OF CARBOLIC ACID ON THE URINE.—Mr. W. A. Patchett reports a number of observations upon a peculiar change of color in the urine, produced by the external application of carbolic acid to a raw surface. A blackish or dark olive-green discoloration occurs in from four to forty-eight hours, and the urine resembles an infusion of tea or digitalis to which a little iron has been added. The discoloration does not appear with any regularity or constancy, and may follow the internal use of carbolic acid, but unless poisonous doses have been given the color is not so deep as that produced by the external application of the acid.—*London Lancet*, August 23, 1873.

TRANSLATIONS.

CARBONIC ACID IN THE URINE IN FEVER.

By DR. C. ANTON ERRALD. Translated from *Archiv für Anatomie, Physiologie, und Wissenschaftliche Medicin*

BY WM. ASHBRIDGE, M.D.

OF late the amount of carbonic acid excreted under normal conditions by patients with fever has been regarded as an important element in the metamorphosis of tissue, and has been determined both by direct and indirect methods. The results obtained by investigators provided with better means of research which give an increase in the amount of carbonic acid exhaled from a patient with fever differ from those of the older observers. A similar result is not given by observations upon animals in a febrile state (*i.e.*, when the temperature is artificially elevated), in whom there is either no increase in the production of the gas in question, or if there is any increase it is but slight and irregular. The importance of the question renders it desirable to support the results already obtained, and to strengthen them by a new series of observations upon febrile patients, conducted by new methods.

Apparently the difference in the results in the experiments on men and on animals can be accounted for by individual characteristics, for it is not possible for the experimenter to reproduce the febrile state so accurately in animals that he can apply his results exactly to cases of fever in human patients. Heretofore, in searching for carbonic acid in the excretions the expired air only has been examined, and the gas contained in the other secretion has been overlooked.

The urine in these experiments was drawn into vessels carefully cleaned and from which the air had been exhausted by the air-pump, and its quantity was ascertained by weight and noted. The quantity of oxygen and of carbolic oxide contained in urine is so small that it was overlooked in the estimates of the amount of carbonic acid present. Numerous observations were made, and the fact most clearly established that for the same individual, *cæteris paribus*, the amount of carbonic acid in the urine in fever is greater than in health, and, further, that the evacuation of carbonic acid in its increase and diminution keeps pace with that of the urea. This parallelism is to be expected, since, although part of the carbonic acid comes from oxidation of the albuminates, another part of it has its origin in the consumption of hydrocarbons and fats, and this latter source is the one which is the more important in health. These results must be looked upon as the expression of the increased metamorphosis of tissue in fever, and, since it has been shown that the carbonic acid has its origin in the tissues and not in the blood, it follows that the increased carbonic acid observed in fever likewise has its source not in the blood, but in the tissues.

DROPSY OF THE FOURTH VENTRICLE.

Translated from *Le Progrès Médicale*, August 2,

BY WM. ASHBRIDGE, M.D.

AT the meeting of the Société de Biologie, July 26, 1873, two cases of dropsy of the fourth ventricle were reported; in both cases death occurred suddenly, and autopsies were made. The first case was that of a woman who, falling suddenly without consciousness, was taken to the hospital, where, after about an hour, during which she had convulsions, she died. At the autopsy, dropsy of the fourth ventricle was found, and,

in addition, hyperæmia of the pia mater, and a dilatation of the fourth ventricle, the walls of which were pushed apart by a considerable quantity of fluid. The ependyma covering the walls was much thickened. The lateral ventricles were also dilated, but in a much less degree.

In the second case the patient was a young girl, 17 years of age, who entered the hospital with the signs of meningitis, but as the symptoms ameliorated she was able to leave. The same symptoms appeared for the second time and again vanished. But on the 10th of July, a short time after she had been observed quietly talking with her companions, she was found dead.

At the autopsy there was found a moderate hyperæmia of the meninges, dilatation and dropsy of the fourth ventricle, with thickening of the lining membrane, and more than the usual amount of fluid was found in the lateral ventricles. In both cases were found the same lesions, and in both there was rapid death, which was due, probably, to compression, as there was a very rapid pulse and rapid respiration, but no elevation of the temperature. The dropsy was probably promoted by the hyperæmia of the meninges, which was established by the autopsies.

THE CENTRE OF THE NERVES OF ERECTION.

By Prof. W. Goltz. Translated from *Archiv für die Gesammte Physiologie*

BY WM. ASHBRIDGE, M.D.

PROFESSOR GOLTZ was induced, by the statement of Eckhard that the nervi erigentes could be followed within the spinal marrow, and even up to the pons and into the cerebrum, to publish the results of investigations of the subject made by himself upon dogs, and which have led him to a different conclusion. He is convinced that the nearest centre from which the nerves in question have their origin is the spinal marrow of the loins. After section of the posterior segment of the cord in the thoracic region, he was enabled to cause erection by reflex influence.

He found also that the occurrence of these reflex phenomena can be checked by irritation of nerves of sensibility.

Further than this, he observed characteristic rhythmical contractions of the sphincter ani in animals whose spinal cords had been cut, which could also be restrained by irritation of certain parts. He concludes that the spinal marrow of the lumbar region contains centres of influence of far more diversified character than has previously been supposed.

CHOLERA AND INTERMITTENT FEVER.

By Dr. Joseph Hilf. Translated from the *Wiener Medicin. Presse*

BY WM. ASHBRIDGE, M.D.

DR. HILF thinks that any one who has had an opportunity of observing cholera in malarial districts where malarial fevers are endemic must have noticed a certain resemblance between these two diseases : both having a hot and a cold stage, being attended by an almost insatiable thirst, and, finally, the occurrence of sweating; and in the so-called pernicious fever the stages of cramps and vomiting are constant, as in cholera. When the causes of the two diseases are compared, a similarity is again noticed, the malarial fever being due to the exhalation of swamps, while he regards the hypothesis that cholera has its origin in the miasma of the delta of the Ganges as the most probable one. He had an opportunity in the year 1855, while stationed in a malarial region of Hungary, of observing cases of cholera during the epidemic of that year, and he was induced by the resemblance alluded to above to adopt the received treatment in malarial fever—*i.e.*, by quinia—in cases of cholera.

His wife, at that time in the sixth month of pregnancy, being attacked with the prevailing epidemic, and all other treatment having failed, he, in the hope of sustaining strength, administered two grains of quinine every hour, and, to his great delight, after the exhibition of the third dose he saw an increase in the temperature of the body and in the number of the beats of the pulse. During the six weeks that the epidemic lasted, out of one hundred and twelve cases treated by tannin and opium, and, when these failed, by quinine, he lost but thirteen cases.

During last year two cases were treated in Pest with the same drug, with favorable results in both cases; and during the present summer numerous cases have been treated both by Dr. Hilf personally, and by others to whom he has recommended the use of quinine, and the results have been uniformly favorable.

THE COMPOSITION OF THE MILK OF WOMAN.

By Dr. Th. Brunner. Translated from *Archiv für die Gesammte Physiologie*

BY WM. ASHBRIDGE, M.D.

THE object with which these investigations were commenced was to ascertain, if possible, whether differences could be observed between the secretions of the two breasts of the same individual, and, if possible, to solve the question whether the constituents of the milk are prepared by the gland itself, or only separated by it from the blood. The women upon whom the observations were made were, with a few exceptions, from the Foundling Asylum in Prague.

The most extreme care was used in conducting the experiments, and some new methods were employed in conducting the quantitative analysis, by which Dr. Brunner thinks he has attained a degree of accuracy not before reached. The results given by him agree with those obtained by previous investigations more nearly as regards the proportionate quantity of sugar than the other constituents. Part of this discrepancy he thinks can be accounted for by the different methods employed, and part is due also to the fact that the women used for his investigations had borne their children some months before, and it appears that the milk becomes poorer as lactation is prolonged with regard to albumen and fat, while the amount of sugar, water, and soluble salts contained remains nearly unchanged. Some of his observations were conducted with a view to comparing the secretion of the two breasts. His results show that there can be a difference in the composition of the milk of the two breasts, but his observations were not numerous enough to justify the drawing of any definite conclusion on the subject.

A Mummy Monster.—Dr. Chas. S. Swazey, of New Bedford, has kindly allowed me to bring some photographs of Peruvian relics, and among them is one of a human dicephalus, closely resembling our specimen; but as it is in a sitting posture and shown from in front, the existence of median limbs is merely to be inferred. It seems that monsters did occur among the ancient Peruvians, and that they were not consigned to scientific investigation, but duly mummified.—*Prof. Burt G. Wilder, in Proc. of the Am. Assoc. for the Adv. of Science.—N. Y. Tribune.*

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 20, 1873.

EDITORIAL.

THE ADMINISTRATION OF CHARITIES.

IN our issue of August 30 is a letter from Dr. Levis, of this city, called forth by an editorial which appeared in our columns in regard to the Wills Hospital. That letter seems to establish the truth of what we hinted at,—namely, that the foundation of the charity is not administered in accordance with the *strict letter* of the testator's will. It is very probable that more good is accomplished by the present use of the money, and that a wider reputation accrues thereby to the memory of the donor; but this does not alter the facts of the case. As legal opinion has given "latitude" to the words of the will, we will not be too carping, and will agree with our correspondent that the instrument alluded to is complied with as far as is *practicable and right.*

We have long thought that great care ought to be practised in departing from the strictest *letter* of the law in these matters; and facts which have recently been brought to the light in regard to the London charities have most strongly confirmed us in this opinion. According to these disclosures, some of the richest and most famous endowments of that great city have been little by little completely perverted from their original purposes, and in the management of others the most reprehensible extravagance, even to the point of impoverishment, has been indulged in. It is stated that the hospital and school endowments should be sufficient to take care of all the sick and educate all the children of the poor; but, in truth, the lower middle classes are ground down to the verge of destitution by the municipal taxes for such purposes. As an instance of the perversion of an educational foundation, it is sufficient to cite the famous Charterhouse school, where it now costs £95 a year for an education, although the school was originally intended for the children of the poor-rate payer.

"Again, the house-rent and establishment charges of seven of the wealthiest city companies alone amount to £164,000 a year, the interest on £2,000,000. And these companies, originally trades benefit societies for men as well as masters (in the old Merchant Taylors' Company we find the 'cissor' or cutter-out side by side with the merchant clothier), have long since eliminated the workman, and have now little more than a nominal connection with the trade they represent."

With the hospitals matters are not much better. The three richest institutions of such nature in London are Guy's, St. Thomas's, and St. Bartholomew's, and of these the latter two were originally workhouse asylums, supported by, and belonging to, the citizens of London. It is said that the new St. Thomas's Hospital will cost, when completed, something like £800 per bed, a sum which at the usual builder's estimate would have given each patient a separate room in a house in Belgrave Square. The little hospital at Poplar, mainly supported by the engineering establishments on the Thames, cost only £30 per bed; the Guards Hospital less than £100. Apply the latter estimate to St. Thomas's, and add £50 a bed for the value of the ground, and there would be a surplus left for pauper infirmaries for 2333 patients. Nor is it clear that the results of all this costliness are proportionate to the outlay. The Poplar Hospital in 1871 had only 14 deaths among 2774 patients, and not one instance of pyæmia. Of lying-in cases, which alone admit of an exact comparison between the workhouse infirmary and the hospital, the deaths in a model hospital ward during six years averaged 1 in 23; in eleven workhouses for the same period, *nil* in 2413.

GLYCERIN AS A MEANS OF DISGUISING MEDICINES.

WE desire to call the attention of our readers to the use of glycerin as a means of disguising medicines, especially those of an oily nature. Some time since it was announced that if castor oil be mixed with an equal part of glycerin and one or two drops of oil of cinnamon to the

dose, it can scarcely be recognized. We have used this mixture a great number of times, and can confirm all that has been said of it. Children take it out of the spoon without difficulty. We have given it to doctors without their discovering that they were taking castor oil.

In typhoid fever and other diseases in which turpentine is indicated, patients often object very much to its taste. The addition of half an ounce of glycerin to a six-ounce emulsion disguises almost completely the turpentine, especially if a drop of oil of gaultheria or of other volatile oil be added for each dose.

No doubt the principle is capable of wide extension. It is said that cod-liver oil may be disguised with glycerin and whisky; and Dr. Herbert L. Snow writes to the *British Medical Journal* that an addition of a small quantity of glycerin (about half an ounce to an eight-ounce mixture) will altogether obviate the sensation of astringency produced by the chloride of iron dissolved in syrup.

POSSIBLY, when, a few numbers back, in commenting upon Dr. Goodell's article, we urged the necessity of public *fosses d'aisance*, we asked for too much. The public mind—certainly the municipal mind—is not yet prepared for such an advance towards the convenience and comfort of the citizen public. The laying out, building, and ordering of a great city, the securing to its inhabitants adequate supplies of food and fuel, pure water, brilliant and cheap light, as well as adequate drainage and clean streets, are a great work,—so to speak, a process of evolution,—and require time. But in the primordial germ of "Commit no Nuisance," which has so long sufficed us, signs of change are seen. Increased function—we have no longer deserted lanes, our back streets are closely settled, and abound in women and children—calls for increased and higher organization. We hail with delight the coming comfort; but we must not forget that in evolution nothing is done *per saltem*. To skip at once from the dodging into a chance stable or board-yard, or sneaking up a dark alley at the imminent risk of being confronted by stray passers, or the worse choice of going into a vile dram-shop in order to find a place to relieve an all too full bladder,—experiences that few who have served in the southwestern district of the Philadelphia Dispensary have escaped,—to skip at once from such wretched devices to conveniently arranged, comfortable, cleanly public privies would be too great a leap. But it is not too much to ask for simply constructed, unobtrusive *pissoirs*,—little iron structures properly screened and kept pure by water constantly trickling over an enamelled surface to join the sewer by means of a trap. These could be placed at convenient points everywhere, and would prove a blessing to all classes of men whose occupations compel them to go from place to place for many successive hours without opportunity other than we have hinted at to relieve their bladders. Physicians would be by no means the only gainers; a score of occupations suggest themselves whose followers would gain by it, besides those who from vesical disease, from diabetes, etc., etc., are compelled to frequent micturition. Moreover, we are becoming a beer-drinking people; and, much as has been said in praise of inspiring, bold John Barleycorn, it is a cheering sign of the times when a people changes spirits for malt as an every-day beverage. And we all know what comes of beer! We have no wish to lower the delicacy of feeling on certain subjects, of which, as Americans, we may be proud. Quite the contrary. We plead for no such unblushing boxes as are to be found on the sidewalks of many streets in Paris. What we desire is the supply of a long-felt want, which is compatible with all decency, and the removal of one of the commonest and most frequent temptations of working-men to go into rum-holes.

OUR readers will no doubt remember the hysteroidal sufferings of a certain London journal on the occasion of the appearance of "*The Medical Times*," due to our having adopted a portion of its title. There lies on the table before us a recent periodical which we fear will cause a relapse of that affection, which was cured by the insertion of the word "Philadelphia" into our title. Canada now boasts the possession of "*The Medical Times*." It certainly would facilitate the understanding by readers of the sources from which quotations may be taken if *The Medical Times* would follow the example of its older brother, and adopt "Canada" as a surname. When we say, however, *The Medical Times*, our readers may rely that we don't mean either *The Lancet* or *The Medical Times and Gazette*.

EUROPEAN papers state that in Munich, where several cases of cholera have occurred, the rooks and crows which before flew about the steeples and through the trees of the public promenades have all emigrated. The same thing happened during the cholera seasons of 1836 and 1854.

According to Sir Samuel W. Baker ("Eight Years'

Wanderings in Ceylon," chap. viii.), the same phenomenon occurred at Mauritius, where the martins, which exist in immense numbers the year round, wholly disappeared during the prevalence of the cholera.

CORRESPONDENCE.

A "NEW" USE OF ETHER.

To the Editor of the Philadelphia Medical Times:

DEAR SIR:—I note in some of the daily papers an extract from the London *Lancet*, having reference to the etherization of patients for the purpose of preventing the suffering incident to removal from one place to another, and speaking of it as a new idea.

I am sure there must be many readers of the *Times* to whom, as to the writer, this is a familiar practice, and has been for years. Many invalids in this city are in this way taken painlessly for miles into the country, or to the sea-side, in the early summer of each year, and returned to their homes in the autumn in the same way.

With chloroform, which has been so exclusively used by the British physicians and surgeons, this plan would of course be highly dangerous; and for this reason, it must be supposed, the idea of anæsthesia for the journeys of invalids comes to them as a novelty.

Respectfully yours,

P.

REVIEWS AND BOOK NOTICES.

Thinkers and Thinking. By J. E. Garretson, M.D. (John Darby), author of "Odd Hours of a Physician," etc. 16mo, pp. 254. Philadelphia, J. B. Lippincott & Co., 1873.

"To know that we know what we know, and that we do not know what we do not know, that," said Confucius, "is true knowledge." This comprises the sum and substance, the all and yet the nothingness, of human knowledge; and this humbling thought is the burden of this little book. With upturned eye and outstretched hand, the author yearns to catch at the meaning of those great problems of life which have baffled the maturest minds of every age. But vain; alas, how vain! Oh, "grand thaumaturgic faculty of Thought," far transcending all things earth-born, nimbly overleaping such hurdles as time and space, and yet powerless, in vesture of flesh, to reach the empyrean of truth!

We can best express our estimate of this book by stating that it concerns itself about those footballs of philosophic conjecture,—the higher truths of life. It begins, in fact, where ends the author's "Odd Hours of a Physician," and is a commentary rather than a complete exposition of the various systems of philosophy. Step by step the reader is guided through the mental labyrinths of those schoolmen who have so broadly thought but so weakly moralized,—men of whom Cicero said, "*nihil tam absurdum, quod non dixerit aliquis philosophorum.*" The shrouded forms of antiquity emerge from the depths of time, and pass before the reader in one stately panorama, unbroken by chapter or section. Their errors the author exposes; their fallacies he points out, but in no carping mood,—it is the lover who chides. This manner of dealing with the sophisms of these *doctrinaires* reminds us of Isaak Walton's advice. "Handle him," writes that quaint angler in his directions for impaling a worm on the hook,—"handle him tenderly as though you loved him."

According to the complexion of the reader's mind will be the lesson imparted by this book. One class of readers will learn from it the folly of the contention between common seekers after truth, who, being alike honest in their intentions, proceed some from *a priori* premises, others from *a posteriori* data. Another will be led to utter thanks for a Bible which has saved them from mistaking for revelation the sentimental inferences of morbid psychological introspections,—thanks for a religion which has overthrown, and ever will overthrow, systems of sociology not based on God and law. A third class will ponder over that "entelechy" which Aristotle discusses, and which the author clothes with the attributes of the soul. The student of Sir William Hamilton will wonder whether he has not at last discovered the mystery of the "non-conditioned;" while the most strait-laced theologian may be led to doubt whether a pure materialism has in it anything more in conflict with his cherished doctrines than the new vocabulary and the unfamiliar terms employed by positive science for logical precision, the differences being not so much in the matter as in the manner.

In the attempt to reconcile positivism with so-called orthodoxy, the author, although evidently at heart a pantheist of the school of Spinoza, feels constrained to adopt the Cartesian system of philosophy. We say "*constrained*;" for however consonant with the phenomena of nature an absolute materialism may be, and however upheld by the subtlest thoughts ever expressed in terms of human speech, there is in man an inner consciousness of an alliance with a higher intelligence, of a relationship with the Infinite, which compels a belief in the existence of a divine personality. Again, there is yet another difficulty. The reasoning employed to carry us into materialism inevitably lands us beyond it into idealism. "If," says Huxley, "the materialist affirms that the universe and all its phenomena are resolvable into matter and motion, Berkeley replies, 'True; but what you call matter and motion are known to us only as forms of consciousness; their being is to be conceived or known; and the existence of a state of consciousness, apart from a thinking mind, is a contradiction in terms.'" Impressed by these difficulties, the creed of Descartes is, therefore, the one adopted by the author: "There is one entity,—God; this entity has produced two others, force and matter: in the first have these others their existence."

At the doctrine of evolution the author has his fling, and that in true Socratic style. "Has Mr. Darwin," he asks, "ever been able to change a pigeon into a gestating animal, or a bullock into a bipedal ruminant? Is there to-day one who may [can] cast the disk farther than the Roman athlete, or one who shall be found able to speak words wiser than [those of] Pericles?" These arguments have their value, but lack, in our opinion, the weight of those which contend that the theory of evolution makes greater demands upon our credence than does the theory of plan; that thus far it has failed to account for the origin of life; that, granting the modification of species by the influence of natural selection and by variations in external conditions, this does not prove any derivation by virtue of an internal evolutional impulse, nor does it consequently invalidate the primitive law of specific generation; that in his imposing position in the animal kingdom, in his gift of speech, and in his mental, moral, and spiritual nature, man bears the indelible stamp of his divine origin;

finally, that the resemblances in nature are but the departures from one general type or model, and, as such, exhibit not so much the modifications of evolution as the handiwork of a *single* Creator,—the mannerism, so to speak, of *one* great mind.

From this imperfect summary it will be seen that this book is well calculated to quicken seed that lies dormant in every brain. A perusal of its chapterless pages can hardly fail to break up the dull round of care and toil, not by beguiling the fancy with cadenced periods and inflated tropes, but by affording food for thought,—calm and philosophic, and yet unsatisfied, because always yearning with quenchless longings after the incomprehensible.

"Sweet Phosphor, bring the day
Whose conquering ray
May chase these fogs away!
Sweet Phosphor, bring the day!"

LECTURES ON MADNESS IN ITS MEDICAL AND SOCIAL RELATIONS. By EDGAR SHEPPARD, M.D. Philadelphia, Lindsay & Blakiston, 1873.

Much as has been written upon insanity, deep as is the knowledge of the specialists, we doubt if there is any subject of equal practical importance upon which the general rank and file of the profession know so little. The subject is not taught, at least that we know of, in our medical schools; the science is embalmed in elaborate treatises which frighten the practitioner from approaching it, so that we doubt if one doctor in ten could tell what are the forms or varieties of the affection. Dr. Sheppard was recently elected to a new chair in King's College, London, for the purpose, evidently, not of producing specialists, but of introducing students "within the precincts of that domain which is peopled alike by the wildest and happiest, the tamest and most mournful, of mankind,"—of giving them just such acquaintance with insanity as would suffice them in the daily duties of general practice. It is the lectures delivered in this course which, having taken the permanent, tangible body of printer's ink, lie before us, and the audience they now address is just such of the profession as those who, five, ten, twenty, or thirty years ago, in the days of their student life, ought to have heard such teachings but had not the opportunity. Looking at the book from the stand-point of a general practitioner, we think Dr. Sheppard has done his work well,—told his story graphically, interestingly, and instructively, and, let us add, honestly.

In the very outset he points out a very serious result of the general professional ignorance,—namely, that commencing insanity is often overlooked, to the detriment of the patient, and that the histories sent up to asylums are often absurdly false, to the detriment of the alienist and the complete shipwreck of his elaborate statistics. He says, "We have no power to alter the record, and it goes, with many other lies, to make up our statistics, which are really nothing more nor less than tabulated falsehoods."

The book is divided into seven chapters: the first discussing general subjects connected with insanity; the second, the nervous system, the pathology of insanity, and various general therapeutic and hygienic means and precautions, such as the Turkish bath, artificial feeding, precautions against suicide, etc.; the third, mania, acute and chronic; the fourth, moral insanity; the fifth, sixth, and seventh, puerperal insanity, general paralysis of the insane, idiocy, and imbecility, respectively.

The description given of a case of mania transitoria is exceedingly graphic, even thrilling; but more space and time ought to have been devoted to the discussion of the diagnosis of this affection, especially the distinctions between it, hysteria, and meningitis, concerning which, we must say, the doctor is very unsatisfactory. The chapter on puerperal insanity is full and good, and we agree with Dr. Sheppard that chloral is *par excellence* the *hypnotic*, which, we may add, is about all it is.

Space is wanting to follow the author through his one hundred and eighty-three pages of very readable matter. We commend the work as being what might be called a popular elementary treatise on insanity for the general profession.

From the typographical appearance of the book, we judge that it is sailing under false colors so far as the publishers are concerned: the clear black letters mark it as of English manufacture. This of course does not detract from, but rather increases, the value of the book to the reader, who, we hope, will get as much pleasure and profit out of it as we have.

THE POPULAR TREATMENT OF CHILDREN, ETC. Annual Discourse before the Massachusetts Medical Society, 1873. By CHARLES E. BUCKINGHAM, M.D.

INFANT FEEDING AND ITS RELATIONS TO INFANT MORTALITY. Reprint from *New York Medical Review*.

It is rather too bad that we cannot come to a universally accepted opinion about the dilution or non-dilution of cows' milk for infants. While one party is convinced that pure milk is none too strong, we find another, of which Dr. Charles E. Buckingham is, we hope, an extreme exponent, recommending a dilution of one to four, and, further, giving a general rule that where curd appears in the evacuations the milk should be steadily diluted till it disappears (or the child). Surely we should be able to decide this question by a moderate amount of systematic investigation. We believe in pure milk, and recommend it with average results. Our professional brother around the corner believes in two-thirds water, and recommends it with results, to him, as satisfactory. Can it be possible that both are nearly right?—that diluted milk given freely and often will do pretty well, that strong milk given scantily and not so often will also do pretty well, and that deviations from either path lead us into trouble?

Both pamphlets before us contain allusions to the variation that exists between the milk of different breeds of cows and cows of the same breed, showing how one cow's milk is very different from one other cow's milk, and how safety exists only in the actual testing of the milk,—the mere name of "one cow's milk" being a soothing deceit. Some English writer—we forget who—recommends a city-fed dairy, which could be inspected, and considers that green food renders cows' milk too laxative in summer for most infants. For another reason we think it worth trying, being of the opinion that age and travel, while they may improve men, have a decidedly opposite effect upon the lacteal fluid.

The article from the *Medical Review* goes more thoroughly into the variation of cows' milk, a subject to which Dr. Buckingham merely alludes; it also bestows its approval upon the rules of the Philadelphia Obstetrical Society for infant management, while it handles some other "rules" with uncovered hands.

ALBUMEN OBTAINED FROM MILK.—M. Schwalbe has found that by adding one drop of the oil of mustard to twenty grammes of cows' milk, the casein is transformed into albumen. If this discovery is confirmed, it will be of great importance in the art of calico-printing.—*Druggists' Circular.*

AN interesting case is reported by M. Dieulafoy, in which an infant, six hours old, was poisoned by a dessertspoonful of laudanum, and from whose stomach the poison was extracted, before it had taken fatal effect, by means of the pneumatic aspirator.

SELECTIONS.

A NEW MODE OF TREATING FUNCTIONAL DYSPEPSIA, ANÆMIA, AND CHLOROSIS.

BY DR. C. E. BROWN-SÉQUARD.

IN 1851 I had to treat a very bad case of dyspepsia, and succeeded in curing the patient by a plan of treatment which, I think, deserves attention. Since that time I have employed it with complete or partial success in a number of cases of dyspepsia, of chlorosis, of anæmia, and also as a means of ameliorating or curing nervous affections caused by gastric disturbances or poverty of blood. I could not say, as I have not kept notes of all the cases, how many times it has succeeded or failed. In a number of instances where failure occurred I have found that the patients had not carefully followed the rules, and that the failure was, at least in a good measure, due to this lack of care. In two cases only some increase of flatulency and acid eructation took place for three or four days, when the plan was given up. In a case of dropsy, attended with anæmia, dyspeptic pains were increased for a week, when the plan was abandoned. These are the only instances I remember in which some bad effect was produced by this plan, and this aggravation soon ceased.

The first patient I submitted to this plan was a scientific man, thirty-four years old, of strong constitution, but from several causes reduced to a lamentable state of health. For about eight years he had been working very hard, taking no exercise, and living almost all the time in a vitiated atmosphere. He slept very little, and usually passed eighteen or even nineteen hours a day writing, reading, or experimenting. His diet was miserable, and, with the object of avoiding the need of much food, he took a great deal of coffee. He gradually, though slowly, became exceedingly weak. His digestion, which had been very good all his life before he began to work so much, had gradually become very bad. He suffered greatly from pyrosis, and a feeling of great distress, and gastric distention after each meal. Acid eructations and gas were frequently thrown up into his mouth, and when he did not vomit he found that his food remained on his stomach so long that in the morning he frequently rejected things eaten the previous day. At last he had to give up work and stay in bed. But no improvement occurred from the rest he then had or from various modes of treatment. His emaciation and weakness and dyspeptic symptoms increased, and his friends decided to have him removed to the country. But he was so weak that he had to be carried in a litter to the railway station. After a few days, finding that he had not improved, I decided to try a radical change of his alimentation as regards the quantity of food to be taken at a time. Instead of *three* meals a day I made him take *sixty* or more. Every twelve or fifteen minutes he took two or three mouthfuls of solid food, chiefly meat and bread. He drank a little less than a wineglass of Bordeaux wine and water every thirty or forty minutes. On the very first day this mode of alimentation was begun, his digestive troubles disappeared, and within a week he was so well that he returned to Paris, not, however, to go to work again, as he had been rendered wiser, but to prepare to go to the sea-shore. He continued the same mode of alimentation for about three weeks, and then gradually diminished the number of his homœopathic meals and increased the amount taken at each of them until in about eight or ten days he came to eat only three times a day, and a full meal at each time. His strength during the first week had become almost as great as it ever had been previous to his illness. Since that time his life has been one of great hardship, which he has borne remarkably well, and dyspepsia has only troubled him in a slight degree rarely and for short periods.

The plan, as stated in the above case, consists in giving but very little of solid or fluid food or any kind of drink at a time, and to give these things at regular intervals of from ten to twenty or thirty minutes. All sorts of food may be taken in this way; but during the short period when such a trial is made it is obvious that the fancies of patients are to be laid aside, and that nourishing food, such as roasted or broiled meat, and especially beef and mutton, eggs, well-baked bread, and milk, with butter and cheese, and a very moderate quantity of vegetables and fruit, ought to constitute the dietary of the patients we try to relieve. This plan should be pursued two or three weeks, after which the patient should gradually return to the ordinary system of eating three times a day.

It is hardly possible to give more detailed rules as regards this hygienic mode of treatment. On the one hand, I have found few persons willing or able to follow it fully. On the other hand, many patients, especially those who have no dyspepsia, do not need to take so minute an amount of food at a time. Besides, it is certain that the quantity of food required varies notably in different persons. Prof. John C. Dalton states that the entire amount of food needed by a man in full health and taking free exercise is: of meat, 16 oz. av.; bread, 19 oz.; fat, 3½ oz.; and of water, 52 fl. oz.; *i.e.*, about 2½ lbs. of solid food and rather more than 3 pints of fluid. According to Dr. Edward Smith and other European hygienists, the amount of solid food and of water required each day is notably larger than that marked out by the able American physiologist I have named. My experience with the patients on whom I have tried the plan of feeding above mentioned shows that the amount of solid food required by an adult is nearly always as follows: from twelve to eighteen ounces of cooked meat and from eighteen to twenty-four ounces of bread. As regards the quantity of fluids I have allowed, it has always been notably less than the amount indicated by Dr. Dalton (three pints) and by Dr. E. Smith (four and a half to five pints).

I hardly need say that, in carrying out the plan I propose, attention must be paid to three points: first, the liking and the disliking of certain things by the patient; second, the importance of variety in food; third, the digestibility of certain things compared with others,—digestibility which varies immensely in different patients. When I found that there was no disgust for a meat-and-bread diet I ordered that roasted beef or mutton, with bread, be the almost only kinds of solid food taken. But most patients were either soon disgusted with this diet or refused even to try it. Having ascertained this, I allowed the selection by each patient of his own dietary, insisting, however, that the quantity of cooked meat should be at least twelve ounces a day. The most varied diet as regards the kind of food can be followed, however, under this plan as well as when one has only two or three meals a day. The only absolutely essential points are that the amount of food taken every ten, fifteen, twenty, or thirty minutes be very small (from two to four mouthfuls), and that the quantity of solid food in a day be from thirty-two to forty ounces, or a little less when, instead of water, the patient drinks beef-tea or milk.

I will not enter into long explanations to show how a marked benefit or a cure can be obtained in functional dyspepsia, in anæmia, and other affections, by this mode of alimentation. I will simply say that the facts I have observed agree with the view that we are naturally organized, like most if not all animals, to eat very frequently, and not, as we do, two, three, or four times a day. It seems certain from the facts I have observed

that functional dyspepsia, when once it has begun (never mind by what cause), is kept up and increased by distention of the walls of the stomach. This fact is already well known, and physicians generally recommend that the quantity of liquid taken be very small, and that the solid food be as nourishing as possible, so that its bulk may be reduced, with the view of avoiding great dilatation by the fluid and solid substances introduced in the gastric pouch. But, although deriving some benefit from this diminution of distention, many patients continue to suffer who might be benefited or cured by the plan I propose.

It may be asked if there is no danger that distention of the stomach by a full ordinary meal, after a patient has followed for two, three, or four weeks the plan I propose, would not be more difficult and a source of greater trouble than before that organ had been allowed to contract considerably during the time this plan has been pursued. Facts answer this question in a way that leaves no doubt. There has never been in the cases I have attended the least trace of an increased trouble due to that cause. Even those patients who have not derived benefit from my plan of alimentation, and among them two who had while following it more acidity and flatulency, have at any rate had no increased trouble after having given it up. It is probable that the good obtained from this plan in dyspeptic patients depends at first on the rest given to the irritated stomach, and subsequently on a great amelioration in the quality of the gastric juice.

In anæmia and chlorosis, not complicated with dyspepsia, the advantage of this plan lies in the rapidity of the formation of blood from the notably increased amount of food that the patient can digest.

I have made but very few trials—and incomplete ones—of this plan in cases of organic affections of the stomach. I cannot but think, however, that it deserves being tried in most of such cases.

Against the obstinate vomiting of pregnancy this plan has already been employed successfully by a number of physicians, and once by myself in a case in which many modes of medical treatment had failed.—*Archives of Scientific and Practical Medicine.*

LIME-BATHS IN MEMBRANOUS CROUP.

IN the *Chicago Medical Examiner* of August 15, Dr. John Bartlett commends the following method of using lime-baths in membranous croup:

"Having formed a small enclosure by covering a clothes-horse with sheets, or by taking advantage of the favorable relation of a door to the corner of a room, so as with bed-clothes to close in a suitable space, the preparations proceed as follows: To one side of the tent, on a piece of old carpet, is placed a small tub; in it is put a common wooden bucket, one-quarter filled with boiling water; at hand is a supply of unslacked lime, and a kettle of boiling water. The nurse and child, or the child alone, if of such age as to remain without an attendant, take position towards the middle of the enclosure, the face of the patient being turned from the tub; by raising the sheet, several pieces of lime, as large as the fist, are placed in the bucket; after a few minutes the evolution of the vapor begins. The physician, through that fold of sheeting forming the door of the tent, frequently takes a view of the steam within, estimating its density by the sight, taste, and smell. It is impossible to indicate the proper degree of this density. I should say it should be somewhat less than that of the cloud of steam escaping from the exhaust-pipe of a steam-engine. The smell and taste of lime should not be too pronounced. The nurse should be instructed to give notice if the steam or heat oppress her, so as to produce a feeling of faintness, sense of suffocation, or irritation of the air-passages. Should the vapor be deemed too dense, its intensity may be diminished by opening the flap of the enclosure, or, if need be, by withdrawing the bucket. The pulse of the patient should be noticed from time to time, in view of the possibility of exhaustion supervening, an event said to have occurred in the practice of some physicians. More lime and hot water may be placed in the bucket as required. The tub is intended to receive any overflow from the bucket, which, in prolonged cases, will require to be emptied."

He further says, "The modus operandi of the agent is uncertain; of course, the simplest theory is that it dissolves the false membrane. Some, as Drs. Meigs and Pepper, refer all benefit from its use to the heated steam evolved. Dr. J. L. Smith suggests that the lime-bath may be an improvement on the steam-bath, in this, that in the latter, on account of the necessity of keeping the room closed, the air soon becomes charged with exhaled carbonic acid, whereas in the former the expired acid is speedily destroyed by the vaporized lime. May it be possible correctly to extend this idea of Dr. Smith's? Thus, the dyspnœa is in great part a result of the inability of the respiratory organs to relieve the blood of its carbonic acid. By using air, as in the lime-bath, charged with a chemical having a remarkable affinity for this acid, may it not be that the pulmonary interchange of gases is advantageously supplemented?

"I have knowledge of four cases of membranous croup treated by lime; of these, two were speedily relieved. In a third, recovery ensued, though the lime-baths were abandoned for the potash treatment, when the child, though very near death, was thought to be a little better. In the fourth case, the disease had existed one week before medical treatment was sought; an indifferent article of lime was inefficiently used for a time; death resulted. In the last two cases, relief was afforded by the baths; and although they were finally abandoned in one case, and imperfectly used and neglected in the other, there was, in both instances, reason to question the curative power of the agent. In none of these cases was the lime used to the exclusion of other remedies. So far as observed, however, improvement was in no wise referable to the medication.

"This mode of treatment is useful in those cases in which the attendant is uncertain of his diagnosis; in which, while he believes he has to do with a case of simple laryngitis, he fears membranous croup. In such instances the lime-bath relieves the distress of the patient, and tends to quiet the anxiety of the practitioner, seeing that he is treating the apprehended disease with no danger of injury to his patient from the *nimia cura medici.*"

GLEANINGS FROM OUR EXCHANGES.

LATERAL ASYMMETRY IN THE BRAINS OF A DOUBLE HUMAN MONSTER (by Prof. Burt G. Wilder).—The four cerebral hemispheres of a dicephalous human monster present such lateral variation in the fissures as are usually noted in a single individual, with certain other features peculiar to a monstrous organization; in one respect, at least, the right hemisphere of the right brain resembles the left hemisphere of the left child. The central right brain is the larger, and this may be connected with the direction of the median leg towards the left side, as if pushed out by the superior power of the right child.—*Proc. of the Am. Assoc. for the Adv. of Science.—N. Y. Tribune.*

Chlorate of Potash and Glycerin Injections in Chronic Dysentery.—Dr. Theodore Mead advocates the injection in chronic dysentery of half a drachm of chlorate of potash rubbed up in half an ounce of glycerin and mixed with three to four ounces of warm water. This should be thrown into the bowel thrice daily, and should be retained as long as possible. He gives two cases as illustrative of the results of this plan of treatment.

1. A young man, æt. 27, was first attacked with dysentery in 1861, and had never been rid of the disease, or had a natural stool, up to June, 1868, when he came under notice. He was then having twenty to thirty stools in the twenty-four hours; was weak and anæmic; muscles atrophied; skin dry; pulse weak, and his general appearance indicated approaching dissolution. The use of opium and whisky, which had always been ordered him in large quantities during the whole of his sickness, was at once prohibited; he was given quinine, iron, strong beef-tea, and forty-grain doses of subnitrate of bismuth suspended in mucilage. The injections were at once commenced, and at first gave him intense pain and were rejected as soon as thrown up, but a decided effect was produced. In a short time the unpleasant sensations subsided, and in a few days he could hold the injections an hour. In twelve days his stools were reduced to eight or ten in the twenty-four hours, and were almost free from pus and mucus. In three months he was able to resume daily work, and has continued it ever since, with no return of his dysenteric troubles.

2. In the second case the dysentery followed an attack of bilious fever, was very obstinate, resisted all the ordinary remedies, and brought the patient to the verge of the grave. The treatment was substantially the same as in the other case, and recovery was complete in two and a half months.—*New York Medical Journal*, September, 1873.

The Antagonism between Atropia and Physostigmia (Prof. Roberts Bartholow: *The Clinic*, August, 1873).—In investigating the therapeutic antagonism of atropia and physostigmia, the following experiments were made:

1. Under the skin of a frog 80 minims of a solution containing $\frac{1}{48}$ of a grain of physostigmia and $\frac{1}{24}$ of a grain of atropia were injected. In fifteen minutes there was complete paralysis of the legs, and partial paralysis of the arms, though sensation was not abolished. Soon after, however, on pinching an extremity or on lightly striking the back, the body and limbs were thrown into violent tetanic spasms. Meanwhile the frog lay relaxed and motionless, and when raised up by the head the limbs hung down perfectly flaccid. He remained in this condition apparently dead for half an hour, when $\frac{1}{4}$ of a grain of atropia was injected. Two hours after this all the toxic symptoms had disappeared, and the frog was as active as before the experiment.

2. Inserted under the skin of a frog $\frac{1}{16}$ of a grain of physostigmia; paralysis noticed in three hours. Then injected $\frac{1}{12}$ of a grain of sulphate of atropia; in a few moments tetanic symptoms manifested themselves on the application of an irritant. When an additional $\frac{1}{12}$ of a grain of atropia was administered, a succession of tremors agitated the muscles, and after these ceased no tetanic spasms could be induced.

3. Injected under the skin of a cat $\frac{1}{8}$ of a grain of atropia, producing in a few minutes dryness of mouth, redness of fauces, dilatation of pupils, partial paralysis of hind legs, diminished sensibility to touch, pain, and changes of temperature, with reflex movements remaining normal. Then injected $\frac{1}{8}$ of a grain of calabarine, causing, after five minutes, contraction of pupils, paralysis of all the muscles of animal life, occasional tremors and slight tetanic spasms, slowness of respiration, which after three hours occurred only once in five minutes; anæsthesia of cornea, and diminished action of heart; the latter, however, continued after respiration ceased. In several other experiments the proportions of the agents were varied, to ascertain how far they were antagonistic as to toxic power. It was found that in corresponding doses physostigmia was more powerful than atropia, as well as slower in its action, and that to obtain a balance of effects enough of the latter must be given to dilate the pupils, and its influence kept up by continued use. Large quantities of both, given together, so overpower the nerve-centres as to destroy life.

The results obtained from the above experiments may be stated as follows: Atropia and physostigmia both produce paralysis; the former by destroying muscular irritability and the excitability of the motor nerves, the latter by paralyzing the spinal cord. They are antagonistic in their action on the sensory nerves,—atropia destroying and physostigmia heightening their sensibility. They are antagonistic in their influence over the respiratory movements,—atropia increasing and physostigmia decreasing them. They are antagonistic in their action on the heart,—atropia exciting the cardiac ganglia and physostigmia paralyzing them; upon the general sympathetic system the same effect is produced, and by virtue of this the pupil is dilated by one and contracted by the other. The exaltation of the reflex faculty noticed in frogs is peculiar, and cannot as yet be explained; atropia when given by itself weakens the reflex faculty, and physostigmia under like conditions destroys it, yet their combined use produces effects which are like those of strychnia, and which come on together with the toxic manifestations of the agents. The tetanic spasms are less marked in warm-blooded animals, but they do occur to a limited extent.

Case of Extra-Uterine Fœtation (Joseph Garland, M.D.: *Boston Medical and Surgical Journal*, July, 1873).—Mrs. C., æt. 32; had been married about nine years, and was the mother of two healthy children. She had had one abortion, after which her menses were regular, and she enjoyed good health. Pregnancy was first suspected in May, 1871, from which time gestation went on without any occurrence of special note, except frequent attacks of pain and discomfort in the region of the uterus, until January, 1872, about the time of expected delivery. At this date slight pains were felt in the back and lower part of abdomen; there were rapid and vigorous movements of the fœtus, and a dark bloody discharge from the vagina; these symptoms soon disappeared, and did not return. Examination revealed a large round tumor reaching from the pubes to the ensiform cartilage, centrally located, and about the usual size, but less resistant than the uterus, containing a fully-developed living fœtus. No fœtal heart-sounds could be heard. Digital exploration gave a contracted os, a long cervix, and in the posterior culde-sac a large projecting surface, sudden pressure on which moved the whole tumor. On March 16, as there were no further signs of labor, Simpson's sound was passed; it entered with difficulty two and a half inches, seeming to impinge upon and then pass by some solid and impacted body. On March 17, peritoneal inflammation set in; this was succeeded by diarrhœa, during which the patient became very weak and emaciated, and the abdomen rapidly decreased in size. At first nothing unusual was noticed in the discharges, but upon inspecting them, on April 24, portions of a decomposed fœtus, both soft parts and bones, were found. When the rectum was examined, the lower margin of an opening was detected in its anterior wall. The last piece of bone was discharged on May 4. After this, notwithstanding the diarrhœa was nearly checked, and

the most sustaining treatment used, the patient gradually sank, and died on the 20th of May, 1872.

Autopsy.—A hard, irregular tumor was found extending from the cavity of the pelvis to the umbilicus, the greater part being to the right of the median line. On incising the mass, an oblong cavity six and a half inches in length by five and a half in breadth presented itself, filled with fœtal bones and a dark putty-like matter. No placenta or placental attachment could be seen. Inferiorly and to the right of the mass was the uterus, twisted on its axis and retroverted; inferiorly and to the left, the large opening communicating with the rectum. Superiorly and anteriorly it was attached to the abdominal parietes, the intestines and the omentum, and was in a gangrenous condition. The walls of the sac were thick and dense, their internal surface being ragged, dark-colored, and sloughing. The bladder was slightly adherent, but otherwise normal. The uterus itself, with the exception of its peritoneal surface, and its posterior portion which formed part of the base of the sac, was in a nearly healthy condition. The left ovary could not be identified, and the left Fallopian tube could not be isolated from the walls of the cavity. The matter contained in the sac consisted of the soft parts of the fœtus which had not escaped per rectum, together with all the cranial bones and a number of the larger bones. The length of the shaft of the femur was $2\frac{3}{8}$ inches, and of the tibia $2\frac{1}{4}$ inches, showing that they belonged to a well-developed nine months' fœtus.

The most probable explanation of this case is, that the impregnated ovum fell into the peritoneal cavity, and, throwing out attachments, developed there; the placenta being perhaps attached to the posterior surface of the uterus.

THE PHYSIOLOGICAL ACTION AND THERAPEUTICAL EMPLOYMENT OF ERGOT.—Dr. S. Kersch (*Betz's Memorabilien*, vol. xviii., No. 5) finds that when a concentrated infusion of ergot is injected into the jugular vein of a dog, the animal becomes restless, howls loudly, and its extremities become perfectly rigid in less than half an hour. Its body is cold to the touch, and the temperature low. If one of the arteries in the limbs be now exposed, it is found to be strongly contracted, firm, and hard to the touch. The pulse-tracings obtained from the arteries show small and short curves, with long intervals between them, indicating that the pulse is slow and the expansion of the artery small. The effect of ergot on the arteries is still more distinctly seen by exposing the arteries of a healthy animal and comparing them with those of a poisoned one. A concentrated infusion of ergot mixed with milk, and administered to pregnant cats, produces similar effects; but the restlessness and cries are more strongly marked, and the symptoms of intoxication are later in appearing. Within two days, at most, the young are expelled. The parent animals die from convulsions and exhaustion. A concentrated infusion of ergot administered to dogs along with milk produces, within three hours, great contraction of the arteries, so that the small ones become quite impermeable, and look like nerves. Ergot likewises causes contraction of the arteries, and consequent slowness and hardness of the pulse, in man. In all the experiments on fasting animals, ergot produced violent retching, and, in most of them, vomiting. When the dose was large enough, almost all died on the fourth or fifth day, from convulsions. Although ergot is much used in hemorrhage after delivery, it is rarely given in puerperal fever; but Kersch was led by an accident to try it in this disease. In two cases which he details, as well as in several others, the best results were obtained; the pulse becoming slower, and the temperature falling shortly after the administration of the remedy. Kersch recommends a trial of ergot in febrile cases arising from various causes.—*The Medical Times of Canada.*

WEANED FROM HYPODERMICS.—A young lady who had been accustomed for a long time to the use of opium applied to an eminent physician to make hypodermic injections of morphia. He commenced by making the injections as desired of morphia and water; by degrees the quantity of morphia was lessened without her knowledge, until within a few days nothing but pure water was injected; after each injection she would lapse into a quiet sleep, in the same manner that she had been accustomed to when under the actual use of morphia. This treatment was continued for several months, during which time tonics had been used, to strengthen the system and bring about a healthy condition after being so long a time under the influence of opium. When he considered it safe to do so, he told her plainly that she had not taken a particle of morphia for several months, and was entirely free from its influence; this statement of course was received with intense surprise, as well as unbounded joy. The lady is to-day entirely free from any desire for opium.

We give below the formula for an "anti-opium pill" which has been used for several years in the English hospital at Pekin, China, and its efficacy proven in numerous instances, but of which we have no actual knowledge:

℞ Henbane, gr. $\frac{1}{4}$;
Gentian, gr. $\frac{1}{2}$;
Quinine, gr. $\frac{1}{4}$;
Ginger, gr. $\frac{1}{2}$;
Camphor, gr. $\frac{1}{2}$;
Cayenne, gr. $\frac{1}{2}$;
Cinnamon, gr. $\frac{1}{2}$.

Soap and syrup for coating.
Three pills a day.

—*The Druggist*, July 15, 1873.

TREATMENT OF OBSTINATE CONSTIPATION.—Dr. Macario, of Nice, in a communication to the *Lyon Médical*, observes that in treating constipation most practitioners confine themselves to enemata, laxatives, or more or less irritating purgatives, which in point of fact rather aggravate than cure the affection. He therefore wishes to make known what he says may be truly termed a "heroic" remedy, which he has employed during twelve years with such constant success that he cannot but regard it as infallible.

Constipation, as every one knows, may be produced either by intestinal excitement with deficiency of secretion (nervous constipation), or in consequence of deficient contraction of the muscular coat of the intestine. Here it is produced by atony or intestinal indolence, which bad anti-hygienic habits have induced and keep up. The prolonged contact of the fæces with the rectum blunts the sensibility of the mucous and muscular tissues, and the synergical contraction of the upper portions of the large intestine either does not take place or does so in an insufficient degree, constipation being the result. In *nervous* constipation the following pill should be given: Pure sulphate of iron, ten centigrammes; Socotrine aloes, five centigrammes; atropine, from one-third to one-half of a milligramme. In the *atonic* form, for atropine one centigramme of powder of nux vomica may be substituted. By the aid of these pills regular stools may be procured, even in the subjects of obstinate constipation due to *ramollissement* of the brain and chronic myelitis with paraplegia. Dr. Macario gives from one to three pills immediately after dinner, the object being to produce one easy, natural, non-diarrhœic evacuation. If more than this is effected, the dose is to be diminished, one or two pills sufficing in most cases. The use of these "antistyptic" pills ought not to be continued indefinitely, a longer interval

being allowed to elapse between their administration in proportion as the constipation diminishes, it being of importance to allow the organs to resume their spontaneous action without any auxiliary. If the constipation returns, the pills can be again had recourse to.—*New York Medical Journal.*

Breech Presentations—Rapid Delivery.—The infant's body is delivered with its back superior, the patient lying on her back. First draw the cord down a little way; then, if the head has passed the superior strait, the face is in the hollow of the sacrum; if not, bring it down, according to the usual rules, as rapidly as possible. Then introduce the index finger of one hand into the mouth of the child, drawing the chin down; at the same time with the fingers of the other hand push the occiput up, thus securing perfect flexion. This accomplished, the face of the child will present at the vulva; and immediately withdraw the finger from the infant's mouth, and pass two fingers into the rectum of the patient, and you readily reach the vertex and use these fingers as a lever, lifting *upward* and *outward*, while a similar movement is communicated to the body of the child with the other hand placed below it. If you are on the patient's right side, your index and middle fingers of the right hand will be against the vertex of the child; if upon your left, those of your left hand. If unfortunately you have failed to deliver the body with the back superior, and you have the face towards the pubes, the same general steps are necessary, save that the finger of your right or left hand, as the case may be, should be *kept* in the child's mouth while the upward and outward movement is made with the fingers on the vertex. This method of delivery is applicable to all cases where the body of the child is born first. By it the head can be delivered in less time than required for the application of forceps, and it is much safer for the mother at least. Pursuing it, I have never lost a child in breech presentation, or in podalic version.—*Dr. Langdon, in the American Practitioner.*

The Treatment of Cholera.—Dr. Fergus, of Glasgow, gives the following rules:

Avoid all depressing passions and exhaustion of nerve-force; avoid brandy, or other stimulants, as they are not preventives; make no change in the usual diet, if that is simple, digestible, and nutritious. Avoid excessive fatigue; if overheated, beware of chill, but see that the skin is kept comfortably warm: should the slightest diarrhœa occur, the patient should *lie down immediately*, and, if chilly, have bottles of hot water placed to the feet and legs, also take thirty drops of laudanum, and if a physician is not at hand, the following recipe may be used:

℞ Oil anise, oil cajeput, āā ℥ss;
Ether sulph., ℥ss;
Liquor acid Halleri (which consists of one part of concentrated sulphuric acid to three parts of rectified spirits), ℥ss;
Tinct. cinnamon, ℥ij.

Give ten drops every fifteen minutes in a tablespoonful of water. The opiate may be given with this *once or twice*, but not more.

The Papillary Representative of Two Arms of a Double Human Monster (by Prof. Burt G. Wilder).—A dicephalous human monster, mentioned in the previous paper, has one right arm and one left arm. The missing arms seem to be represented by a nipple-like papilla, on the line of union of the two individuals. Under this is a median and symmetrical clavicle and scapula, into which are inserted most of the usual muscles. Does such rudiment entitle the monster to the title of *Tribrachian?* Excepting the rudimentary arm, this specimen nearly resembles that described by Prof. Wyman in *The Boston Medical and Surgical Journal* for March 29, 1866. In this, however, the anterior separation was more complete, and allowed the formation of a median and symmetrical arm, like the median legs of this and of that specimen. —*Proc. of the Am. Assoc. for the Adv. of Science.*—*N. Y. Tribune.*

MISCELLANY.

Intravenous Injection of Ammonia in Snake-Bite.

"To the Editor of the *Indian Medical Gazette:*

"Dear Sir:—History repeats itself in science as in other matters. To those curious in the question of the treatment of snake-bite, the accompanying extract from Fontana, nearly one hundred years old, will be interesting and suggestive.

"Yours faithfully,
"J. Fayrer.

"London, 22d May, 1873."

TRANSLATION.

"'Opusculi scientifici de felice Fontana, p. 125, letter N,

"'Addressed to M. Gibelin, Aix en Provence, 10th July, 1782.

"'It is very true that several cases of cure of viper-bites by the injection of spirits of hartshorn (ammonia) into the veins have been reported in our Italian papers, and it is also true that these cures appear surprising and almost miraculous from the manner in which they are presented to us: it appears, moreover, that certain persons take a quiet pleasure in assuring the public that the true specific against the poison has at last been found, that which I have in vain sought for many years, whilst with philosophical candor I have declared the inutility of my long researches on the subject.

"'Truly, I must confess that I did not think of seeking a remedy in "*medicina infusoria*," for reasons that I omit at present, but which you can easily imagine for yourself, nor did it concern me to consider the case mentioned by Valisneri, being a solitary one. . . . It is certainly the case that the vaunted cures are too few to form even a probable proof that this remedy is a specific, and that those cures are due to it, and not to the strength of the individual and to the non-deadly nature of the viper poison. Perhaps one hundred cases would hardly be sufficient to make it certain that spirits of hartshorn is the specific against the venom of the viper: if it were so, the bitten animals into whose veins it is injected should be preserved from death, and the more easily so the larger the dose and the sooner after the bite it is injected. I have employed in my experiments lambs and very large rabbits. The lambs have been bitten twice and even three times; the rabbits only twice. The bites have been inflicted in the thigh, and the spirits of hartshorn has been *introduced into the blood in the jugular vein* immediately after the bite, so rapidly that in some animals only a few moments intervened.

"'The quantities used were twenty to forty drops, doses that could be borne by the animals without fatal effects, as I had ascertained by experiment on animals not bitten; a larger dose would have done harm and might have killed the animals. Three lambs were bitten on the thigh; and all died in less than two hours, one after a few moments.

"'Two rabbits out of nine that were bitten survived ten hours, all the others died in less than one hour. I am aware that a dozen experiments are insufficient to prove the *absolute inutility* of the spirits of hartshorn against the bite of the viper, but they are sufficient to show that we should not place confidence in the few favorable cases cited by the supporters of this remedy.

"'So long as medical men are not experimenters, the art of healing will not make great progress; and it is to this, and nothing else, that it is to be attributed that medicine has remained stationary from the time of Hippocrates until the present, whilst all other sciences have been progressing with gigantic paces.

"'The physician considers to be the remedy of a disease that medicine after the use of which recovery has followed, when really, in sound logic, no other deduction should be made than that the vaunted remedy has not killed the patient. We observe that the physician quietly believes, under the influence of this sort of reasoning, that the sick person would certainly have died had he not treated him, and with this he assumes either that of which he knows nothing, or which is doubtful, if not altogether false; and it is not enough that the sick person recovers, but he must also assure himself that he would have died without the remedy.'"

THE following preamble and resolutions were passed by the Board of Regents of the University of Michigan at a late meeting:

WHEREAS the Legislature of the State of Michigan at its last session re-enacted the law of 1855, requiring the appointment of Homœopathic Professors in the Medical Department of the University; and whereas it has always been claimed by the Board of Regents that the law was an infringement upon the rights and prerogatives of the Board; and whereas the Supreme Court of the State has refused to grant a mandamus requiring the Regents to comply with the law, thereby substantially confirming their action: therefore,

Resolved, That we maintain the position heretofore taken, and decline to make the appointments required by the law.

Resolved, further, That we do this in no spirit of factious opposition to the apparent will of the Legislature, but because we believe the true and best interests of the University demand it.

Resolved, That we reaffirm the former action of the Board expressing a willingness to take official charge of an independent school of homœopathy and connect it with the University, whenever the means shall be provided for the payment of its professors.

THE SHAH'S PHYSICIAN.—The body-physician to the Shah is a Frenchman, Dr. Tholozan, who accompanies him on his travels. He has held this position now for fifteen years. He is a member of the Paris Academy of Medicine, and military physician in the French army. He made himself a good reputation by his works on the origin and development of cholera. His epidemiological papers have given him such a position in England that he was banqueted in Greenwich. His second physician, who also accompanies him, is an Englishman, named Dikson. It was his good fortune to have cured the Shah of an obstinate fever during the absence of his physician in Europe.—*All. Wien. Med. Zeit.*, July 1, 1873.—*The Clinic.*

ENDOWMENT OF A MEDICAL COLLEGE.—James Johnston, of Indianapolis, has endowed the Medical College of the Northwestern Christian University (Indiana) with half a million dollars and a site for its location.—*The Clinic.*

WE regret to see that the intention is announced of discontinuing the *Madras Monthly Medical Journal.* This excellent monthly has apparently succumbed to the competition of more frequently published papers, such as our able contemporary the *Indian Medical Gazette.*

MR. WILLIAM MAC CORMAC has been appointed successor to Mr. Le Gros Clark as Surgeon to St. Thomas's Hospital.

NOVEL ADVERTISING.—The following appeared in the *Cincinnati Commercial* of August 26:

"BIRTHS.

"ANDERSON.—August 25, to Mr. and Mrs. Lang T. Anderson, a daughter; weight 12¼ pounds. Thanks to Dr. Comegys."

MR. BROUGHTON, the Government quinologist at Ootacamund, in a report to the Chief Secretary, denies that Eucalyptus globulus contains quinine, quinidine, cinchonidine, or cinchonine, in any such proportion as has been asserted.

EXTRAORDINARY FATALITY.—According to the report of the Board of Health of St. Louis, there were two hundred and ten deaths from *cholera morbus* in that city from June 21 to July 19, inclusive. While extending our sympathies to the citizens of St. Louis, we would suggest to the Board of Health the propriety of importing a rural physician to give them a few lessons in diagnosis and treatment.—*Leavenworth Medical Herald.*

THE reports of M. Nélaton's health are this week much more favorable.—*British Medical Journal*, August 30.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM SEPTEMBER 9, 1873, TO SEPTEMBER 15, 1873, INCLUSIVE.

WOODHULL, ALFRED A., ASSISTANT-SURGEON.—Granted leave of absence for twenty days, with permission to leave limits of the Department. S. O. 157, Department of the South, September 6, 1873.

BYRNE, C. B., ASSISTANT-SURGEON.—Granted leave of absence for sixty days, with permission to apply for an extension of thirty days. S. O. 182, A. G. O., September 11, 1873.

SATURDAY, SEPTEMBER 27, 1873.

ORIGINAL LECTURES.

CLINICAL LECTURE ON CHRONIC CORPOREAL ENDOMETRITIS.

BY F. H. GETCHELL, M.D.,

Clinical Lecturer on the Diseases of Women and Children in the Jefferson Medical College.

GENTLEMEN,—We had before us this morning Miss B., aged 23, by trade an artificial-flower-maker, and by listening attentively to the history of her troubles, and by a series of questions, we learned from her that she had been out of health for the last three years.

Her first complaint was of her monthly sickness. She told us that she menstruated regularly as to the time, but that the discharge was of only one or two days' duration, the amount very scanty, and the pain excessive. She said the pain began two days before the menstrual discharge, and continued some hours after it had stopped, but that it was somewhat less severe after she began to menstruate than for the two days before.

You remember she told us that she was obliged to keep her bed from one to three days each time she was sick, and that her mother gave her "gin and tansy, hot-water and mustard foot-baths, and opened her bowels with castor oil," and although she experienced some relief from this treatment, her sufferings were still very great, and after it was over she lived in anticipation of the agony she knew she must go through the next month. She has headache sometimes in the afternoon, but is not very much troubled with it. She is annoyed with indigestion to some extent, and her bowels are constipated. She has more or less pain all the time in the lower part of her back, and it fatigues her very much to walk, and the back-ache is much worse after a long walk or any unusual exertion. In fact, she said she felt tired most of the time, and were it possible for her to follow her inclination she would lounge about the house for the entire day.

On examining this patient with the finger, speculum, and uterine sound, we found, with the exception of a slight whitish discharge exuding from the os, that part of the uterus to be seen through the speculum to be in a normal condition. When making the digital examination, if we pressed the cervix against the walls of the vagina it gave her no pain, but if I placed one hand above the pubis and with two fingers in the vagina compressed the entire uterus, she complained of great pain. On introducing the sound it met with but slight obstruction at the os internum, and caused no pain until the end of it was pressed gently against the mucous lining of the uterine cavity; but this gave her great pain when it touched the sides or fundus. The withdrawal of the sound was followed by a slight discharge of bloody mucus.

She complains of a leucorrhœal discharge that she has most of the time, but which is more profuse just before, and just after, her menstrual periods.

You will remember that at our last lecture I told you that inflammation of the parenchyma of the uterine neck was the most frequent uterine disease among women that had borne children; and I now tell you that I believe the case I bring before you to-day—which is chronic inflammation of the mucous membrane of the uterine cavity—to be the disease of the uterus oftenest met with in unmarried women, and in married women who have never been pregnant.

You will often be asked, Why do unmarried women have womb-disease?

There are a variety of causes given in your books that may bring a woman to this unfortunate condition; but instead of consuming time in going over the long list of possible causes, let us look for a moment at the most frequent or principal cause,—namely, imprudence during menstruation,—and see if we cannot convince those who think there is no reason why an unmarried woman should have uterine inflammation that they may be mistaken. You heard me question the patient with regard to her habits of life before she was troubled as she now is; we asked her if she made any difference in her clothing, or took any less exercise, while she was menstruating. She said she did not; and then by questioning her we found that, as she was obliged to work through the day, night was the only time she had for recreation; and she told us that she was in the habit of attending several public balls every week during the fall and winter; that she made no difference during the week she was menstruating, but dressed herself in thin clothing, went to balls, and danced till a very late hour, often reaching home, after a long walk through the snow, with draggled clothing and wet feet.

It is not among the lower classes only that you will find imprudence during menstruation, and its unfortunate results, but you will often be called to attend the daughters of indolence and luxury. Not only is their entire life an unnatural one, but they too go to parties while menstruating, dressed in a ridiculous fashion, and remain standing for hours in overheated, badly-ventilated rooms, then adjourn to the cooler hall, or to a seat on the stairs in a direct draught, for a chat with a young man who waltzes exquisitely and displays his classic brow to the best advantage by parting his hair in the middle. I need not tell you that tight lacing has anything to do with uterine disease, for all the women in this country wear their clothing very loose. If you think this is not true, why, ask your first young lady patient that you suspect of lacing tightly, and after a full expiration she will, by contracting the muscles, draw in her abdomen, and then run her hand under her corset, and say, "Look there!" when, if her corset-lacings were to break, the explosion would be equal to the popping of a bottle of soda-water; and when this young lady gets out of bed in the morning, her maid will tell you that the corset-marks of the night before can be plainly seen about her waist.

Cases of internal metritis do not all present the same symptoms: while the menstrual discharge is generally scanty and of short duration, there are cases in which the discharge is profuse, and continues for a longer time than in health. Some of the patients suffer much more than others. You remember we had a young girl before us at our last lecture, who told us she had had a convulsion every time she menstruated for the last thirteen months. Females who suffer in this way are often hysterical, and most of them are exceedingly nervous. The pain in the back is rarely absent, and sometimes is very annoying; and they all have more or less leucorrhœa.

To relieve the intense pain at the menstrual period I think you will find it best to give the patient full doses of morphia at once. I am in the habit of giving a pill composed of one-fourth of a grain of sulphate of morphia, one grain of camphor, and two grains of the extract of hyoscyamus; but it is from the local applications made during the absence of the catamenia that you expect permanent relief. Although general medicinal treatment alone is powerless to subdue this disease, you must not neglect to avail yourselves of so powerful an accessory to the local means employed. You will find among all classes that hygienic laws are daily violated, and you must include in your treatment of these cases not only such medicines as in your judgment are required, but you must not fail to give such dietetic and hygienic directions as may be required to improve the general health of the patient.

The reason the so-called local treatment of this condition is so often unsatisfactory is not that the disease is incurable, but that there has really been no local application made. There is no doubt that many of these patients have had a stick of nitrate of silver passed up the cervical canal time after time, and, while that may be proper treatment for cervical endometritis, it is worse than useless if it is the mucous lining of the cavity of the body of the uterus that is inflamed, for none of the application goes above the os internum. Now, as you all know that the distressing symptoms of inflammation of the lining of the cervical cavity are relieved by alterative applications, the fact that I desire to impress upon your minds to-day is that the inflammation of the mucous lining of the cavity of the body of the uterus will disappear just as surely if the proper remedies are applied to the parts diseased. The first step in the treatment is to dilate the cervical canal; this may be done at once by the uterine dilator, or by the slower action of the tent. Although a little time is lost by using the tent, it is by far the best method, and the only one I recommend you to employ in the treatment of these cases. The sponge-tent is perhaps the best, provided you can introduce it without difficulty; but, as it must be passed through the internal os, the resistance met with at this point is often considerable, and for this reason I have found the laminaria-tent, on account of its firmness and small size, much easier to introduce; and as the amount of dilatation required is not very great, I advise you to use it if you find any difficulty in introducing the sponge-tent. Having dilated the cervix, you introduce the vaginal speculum, and with a wisp of cotton twisted around the end of a probe remove the mucus from the uterine cavity; then with a sable brush you paint the entire cavity with the alterative you have selected for the purpose. Nitrate of silver is highly recommended; but, while I prefer it for cervical endometritis, I very seldom use it above the os internum. I have invariably been disappointed with it in the treatment of internal metritis, while with iodine I have had every reason to be satisfied. The formula I use is—

℞ Potass. iodidi, ℥ss;
Iodinii, ℈iv;
Glycerinæ, ℥j. M.

The application may be made every eight or ten days; it gives but little pain, and the patient is required to keep her bed but one day. The length of time required to relieve these patients of course depends very much upon circumstances: while some will menstruate without pain after a few applications, others will require treatment for a much longer time before relief is experienced, and in some cases you will be obliged to resort to more powerful applications. After applying the above a number of times, if there is no improvement, I then use nitric acid; there is no danger in applying this powerful caustic to the uterine mucous membrane; at any rate, I have often applied fuming nitric acid without the slightest bad effect, and its remedial power in these cases is remarkable. In using the nitric acid, care should always be taken to protect the cervical canal: this may be done by passing the probe, with the wisp of cotton saturated with the acid, through a glass tube, a piece of a large-sized gum catheter, or through the ordinary uterine speculum. The nitric acid should be applied at longer intervals, and the patient must remain at rest in the horizontal position till all fear of inflammatory action has passed. It may appear singular to you that an inflammation of a mucous membrane alone should remain for so long a time and cause so much discomfort, and also that the parenchyma is not involved; but if you will recall your anatomy for a moment you will remember that the lining membrane of the uterine cavity is totally unlike the mucous membrane that is found in other parts: so thick is it that it makes up nearly one-fourth of the uterine wall, and when once it becomes the seat of chronic inflammation there is little or no hope that it will subside spontaneously.

ORIGINAL COMMUNICATIONS.

A CURE FOR EPITHELIAL CANCER.

BY GEORGE G. BREWER, M.D.

WHATEVER tends to increase our capability of coping with a formidable disease cannot be uninteresting to the medical profession. Although cancer is a common disease, and one with which the

surgeon and pathologist is familiar, it is a lamentable fact that it often baffles all treatment. I have always thought that the surgeon's knife was the proper and only treatment for cancer of every description. But my experience in treating an epithelial cancer lately has greatly changed my opinion. The subject of the case was a gentleman fifty years of age, stout and healthy. An epithelial cancer about the size of a hickory-nut located on the cheek near the ear. He consulted other medical gentlemen, who confirmed my opinion and advised him to have it removed. At his request, I removed it with the knife. Part of the wound healed in a few days, but the upper portion soon sprouted out with the cancerous disease. I then applied caustic potassa, not only to it, but to a considerable margin around it. In about ten days after the sloughing was over I found that the entire margin had taken on the cancerous disease, and my patient was in a worse condition than before the operation. At my request, he consulted several surgeons, who objected to operating any more, for fear of enlarging the cancer, and advised a soothing treatment,—poultices of bread and milk. This was followed without benefit for six months, when a friend gave him a recipe which I did not object to his using:

Chlor. zinci, gr. viij;
Bloodroot, gr. v;
Starch, gr. viij.
Make into a paste with honey.

The cancer was at this time nearly as large as a hen's egg. After applying the paste for two weeks, he called to see me. I found it had diminished to half its former size. I advised him by all means to continue it. After a month's use of the remedy, the cancer was not larger than a dime. He continued to use it until the disease was cured. There is at this time nothing but a cicatrix, where before was a large epithelial cancer. I report this case for the purpose of calling the attention of the profession to this remedy in epithelial cancer, and do recommend those who have such cases to treat to give it a trial.

258 West Fayette Street, Baltimore.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by John B. Roberts.

FRACTURE OF THE CLAVICLE BY DIRECT VIOLENCE—THE POSTURAL TREATMENT.

A MAN fell from a loaded cart, fracturing his left clavicle near its sternal end, by the wheel passing in a vertical line over his chest. The clavicle is fractured more frequently than any other portion of the skeleton, as it is a delicate bone with two curvatures, is subject to powerful muscular action, and is so placed as to receive the transmitted force from blows upon the shoulder, elbow, and hand. It is sometimes broken by muscular effort, as in a case seen by Dr. Levis, where a woman sustained fracture of both clavicles in trying to lift a heavy child with each arm. In another case a man broke the bone in the exertion of raising himself from the ground by grasping an overhanging branch of a tree.

Usually the clavicle is broken at the outer part of the middle third, or at the junction of the middle and *outer* thirds, for in this situation the bone is thinnest, and has the greatest amount of curvature and the least ligamentous and muscular support. There is a sort of intermuscular space between the trapezius and deltoid insertions externally, and the sterno-mastoid and great pectoral origins internally.

In this instance the injury is the more rare result of *direct* violence, and the fracture is found exactly where the force was applied. The deformity produced by the displacement of the fragments is perceptible to the eye, and can be distinctly traced by the finger. The outer fragment is drawn downwards, forwards, and inwards by the weight of the arm and muscular action, while the inner one is drawn slightly upwards by the sterno-mastoid.

Of all fractures, that of the clavicle is most difficult to cure without deformity, for the reason that the application of efficient extension in the line of the long axis of the bone is impracticable. Whatever form of apparatus is used, there is always more or less displacement remaining; and it is doubtful whether in oblique fracture a cure without deformity is ever attainable.

The best results seem to be accomplished by simply keeping the patient in the supine position on a flat, hard bed, with the shoulders unsupported by pillows, but with the head somewhat elevated to relax the sterno-mastoid muscle, which tilts up the inner fragment. This treatment can be rendered still more efficacious by placing a weight, such as a bag of shot or sand, on the front of the shoulder, fastening it in position with adhesive strips to keep the shoulder, and with it the outer fragment, pressed backward.

The surface of the bed acts also as a splint, by making pressure on the angle of the scapula, and so giving a leverage which throws the upper part of the scapula upwards and backwards; of course carrying with it the outer fragment of the broken clavicle. This influence of the scapula in overcoming displacement can only be effected by treatment in the horizontal position.

As the clavicle is a spongy and vascular bone, consolidation soon takes place, and the patient need not be obliged to keep his bed more than a couple of weeks. If the union be not firm at the expiration of that time, some form of supporting apparatus can then be applied, and the patient allowed to go about. The general objection to this efficient plan of treatment is its irksomeness and restraint, and its inapplicability to restless individuals and to children; but it can be well carried out in adults under the discipline of a hospital.

In the present instance, as the man returns to his home, and will be treated as an out-patient, the apparatus known as Levis's apparatus for fracture of the clavicle is applied, which fulfils the indications as effectively as is possible, and is more comfortable to the patient than any other.

Dr. Levis stated that in fracture of the clavicle in young children, as the bone is short in comparison with the width of the chest, and there is but little tendency to displacement from muscular action and the weight of the shoulder, he relied on the simple plan of keeping the arm and shoulder supported by broad strips of adhesive plaster, which should be kept on for two weeks, and then replaced by a simple handkerchief-sling.

UNUNITED FRACTURE OF THE TIBIA—TREATMENT BY PERFORATING THE BONES AND CARTILAGINOUS CALLUS.

A woman, aged 40 years, sustained a fracture of both bones of the right leg, in the lower third, fifteen weeks ago. The fibula united without unusual delay, but the

fragments of the tibia failed to consolidate, and at this time a false joint exists between the ends of the bone at the point of fracture. The unnatural mobility is somewhat restricted by the united fibula acting as a splint to the larger bone, but the amount of motion is nevertheless considerable.

There is evidently a mass of cartilage surrounding and uniting the fragments, in which, from some unknown cause, bony matter is not deposited. This case differs from those more rarely seen, in which there is an absolute deficiency of uniting material of any kind, which condition is that to which the term *false joint* is more correctly applicable. The present case is properly an illustration of simply a delay or check in the process of union.

In cases of delayed union a highly nutritious diet is proper, and when the fracture is in the leg the limb should be allowed to hang down below the rest of the body, in order that blood may be fully supplied for the reparative process. It is probable that this *natural position* of the limb would, if more generally resorted to, avert the permanent condition of false joint in fracture of the lower extremities. With such object the leg may be encased in some form of fixed dressing, and the patient allowed to walk on crutches.

Osseous consolidation will generally be insured, in cases of delayed union, by making strong friction of the broken ends upon each other, and, at the same time, bending or breaking up the indolent cartilaginous callus. Such treatment is, however, inapplicable here, on account of the restriction of motion caused by the fibula, as a violent effort might re-fracture its recent bony union.

The plan determined on is the repeated perforation of the ends of the fragments and of their cartilaginous surroundings with a bone-drill, which will excite renewed action in those tissues. The instrument is inserted through but two points in the integument, but it is several times re-entered in the bones, and traverses the fractured extremities in a number of radiating directions. Some inflammatory action will probably be excited, and with it the completion of bony consolidation is hoped for.

After completion of the drilling operation the limb will be encased in a permanent or immovable dressing. For this purpose the Bavarian dressing of plaster of Paris is the best, from its ready application and removal; but bandages stiffened with starch or silicate of soda may be available.

JEFFERSON MEDICAL COLLEGE.

CLINICAL SERVICE OF PROF. DA COSTA, SEPT. 29, 1872.

Reported by W. H. Webb, M.D.

ANEURISM OF THE THORACIC AORTA.

HENRY S., 45 years of age, resident of Wilmington, Delaware, moulder by occupation, presented himself, with the following history:

Had always enjoyed excellent health until two months previous to the date of his present illness; was not strictly temperate. About two years previous to his presentation at the clinic, he received a blow upon the left breast just above the base of the heart; since which time he dates his present illness. It was followed by a smothering, particularly when recumbent, and this was always worse at night: he was not short of breath at other times. The attacks of dyspnœa would last from ten to twenty minutes, and some nights they would be so severe as to prevent him from going to bed. Two months previous to the accident he had muscular rheumatism, and six months after, the above symptoms continuing, he noticed a swelling and soreness on the left side, and about the middle of the chest, with no weight, but a sense of oppression. The oppression has become worse, and he is seldom free from it. He now also has weak spells, which come on when he is worn out by the oppression. He has pain over the cardiac region generally, also pain in the spinal column about opposite this region; the pain is burning in character, worse on pressure over a sore spot near the left shoulder, but not elsewhere. The dyspnœa continues, and still prevents his taking the recumbent posture, except at long intervals.

He is thin, having lost forty pounds in the last two years. Color is sallow; expression is anxious. Pulse 105, full; this pulse is very feeble, small on the left side, very full on the right side; pupils both react to light, no material difference between them.

He has some difficulty in swallowing solid food, but has greater difficulty in swallowing liquids, which often regurgitate.

His respirations are 30 per minute; tongue very much coated; appetite poor; bowels mostly loose; urinates freely, and urine is free from albumen.

The swelling, which appeared two years ago, was at first higher up than at present; it is large, occupying nearly the whole cardiac region, more particularly the centre. A marked swelling exists at the second intercostal space, and the second rib is prominent and out of place; the most obvious swelling, however, is between the third and fourth ribs.

The hand placed over the swelling finds two distinct pulsations: the first is heaving and long, the second is short.

Measuring from over the centre, the tape passing under the axilla, gives 19½ inches on the left side, 17½ inches on the right side; two inches below the nipple the left side is 16½ inches, the right side is 17¼ inches.

Auscultation.—Passing below and going down under the nipple and within, the heart-sounds are heard, the first rather dull, both confused; impulse moderately forcible. Heavy sounds, different from those of the heart, are heard over the mass; the second sound is dull, lacking sharpness, there being no murmur or thrill. The stethoscope being placed over the carotids, there is a dull sound with the expansion of the artery on both sides, but the right carotid beats more forcibly than the left; no murmur is perceptible.

The dulness does not extend below the nipple. Percussion could not be accurately carried out, in consequence of the severity of the pain in the thoracic walls.

Posteriorly we perceived the pulsation with a very faint murmur; the pulsation was distinctly felt over the spinal column somewhat above the point opposite the spine of the scapula.

He was somewhat hoarse, but his voice was not otherwise altered.

The position assumed by the patient, and the one that was most comfortable to him, affording the least pain, was both striking and peculiar: it was that of squatting or stooping. When in bed he would lie upon his abdomen or right side; he could not lie upon his back or left side, owing to the severity of the pain produced by either of those positions.

Diagnosis.—Aneurism of the aorta.

Treatment.—Potassii iodid., gr. x, tinct. aconiti rad., gtt. i, syr. aurantii cort., aquæ, ää ℥ss, every four hours.

[In two months after being under the above treatment he expressed himself as being free from pain, when he resumed his occupation, at which he continued for a few months, when he was obliged to give it up, owing to weakness.

During the interval of the patient's visit to the college, and at the time of his death, July 21, 1873, he was under the charge of Dr. S. L. West, of Wilmington,

Del., through whose influence and kindness I was enabled to make the post-mortem examination, which was made twenty-four hours after death.

There were present at the examination Drs. S. L. West, C. W. Jones, C. W. Kirchner, and E. C. Dunning.

On opening the thoracic cavity the aneurismal sac was found to be closely adherent to the surrounding parts. There were strong attachments to the sternum, with erosion of about two inches at the posterior and upper part, the adhesions extending to the clavicle.

The aneurismal sac was torn somewhat in detaching it, its walls being very thin. It extended from the semilunar valves of the aorta, involving all portions of it down to the thoracic portion, the ascending portion being particularly dilated, its walls apparently losing their identity as composing a blood-vessel, being very rough on their interior and very thin. The transverse and descending portions were dilated to more than twice their normal calibre.

The sac extended upward, but encroached principally upon the left thoracic cavity, displacing the heart and compressing the left lung to about one-fourth its normal size; the structure of the lung was very dense, and gave evidence of having been in that condition for a long time.

No erosion was found of either the clavicle or the first or second rib, though the adhering parts of the two latter had to be removed with the mass. The costal cartilage of the second and third ribs of the left side, as also the intercostal muscles for the space of three inches over the mass, were totally destroyed.

The tumor overlapped the third rib, and in the sac-wall was included two inches of its sternal extremity; being very brittle, it was broken off in removing the specimen; the surface is very much eroded, being less than half the usual thickness, and has the appearance of necrosed bone.

The sac was also closely adherent to the vertebral column, but the vertebræ were intact.

The sac contained closely adherent to its walls—and particularly the anterior—a large, broad, laminated, fibrinous clot, varying in its color from a dusky pink to a deep red, and also varying in its density from the apparent recent clot to the solid fibrinous deposit.

If the sac was entirely empty it would contain nearly a half-gallon.

The pericardial sac contained about a pint of serous fluid, in which was found what appeared to be quite a recent blood-clot, which did not mix with or even color the serum. It apparently came from an oblique longitudinal rent in the walls of the aneurism, one inch and a half long, about one inch above the semilunar valve; the rupture extended through the fibrinous lining of the aneurism.

The heart was rather smaller than normal; its walls were very soft and flabby, and were fatty; the valves were slightly opaque, but otherwise normal. There were no signs of inflammation.

Fluid in the pleural cavities only amounted to a few ounces.—W. H. W.]

Dr. St. Clair Gray calls attention (*Glasgow Med. Journal*) to the little value of an unruptured hymen as proof that rape has not occurred. He relates the particulars of three cases in which the hymen was found persistent in prostitutes. These three cases were found among about 1500 who, within the last few years, have applied for admission to the Glasgow Magdalene Asylum, Lockburn, Maryhill; and should subsequent experience establish this as the precise proportion, viz., 1 in 500, it will considerably affect the significance of persistence of the hymen as an evidence or a sign of virginity.

TRANSLATIONS.

NEW INVESTIGATIONS UPON THE PROTOXIDE OF NITROGEN.

By MM. le Doct. Jolyet and T. Blanche. Translated from *Archives de Physiologie* for July, 1873,

BY FRANK WOODBURY, M.D.

In view of the conflicting opinions regarding the physiological effects of nitrous oxide gas, none of which can at the present time be considered as established, Messrs. Jolyet and Blanche have recently instituted a series of experiments to determine with precision the following questions:

a. Can the protoxide of nitrogen be regarded as a supporter of respiration?

b. Has it anæsthetic or other qualities capable of being utilized in medicine?

a. Is the protoxide of nitrogen a respirable gas for plants and animals?

Plants.—We endeavored first to determine whether grain would germinate in a medium of pure protoxide of nitrogen, and, if germination had already commenced, whether it would continue under these conditions. From the experiments of Saussure it is known that the germination and development of plants are impossible in a medium containing no oxygen; seeds never sprouting in nitrogen, hydrogen, carbonic acid, etc. We then came to consider whether nitrous oxide—a gas unstable and rich in oxygen—would be able by that oxygen to support the respiration of plants. We therefore placed seeds of cress and barley upon a damp filter-paper in an atmosphere of pure protoxide of nitrogen. At the end of nine days in one experiment, and five days in another, the seeds had not even commenced to sprout; while other seeds, under the same conditions, but in ordinary atmospheric air, entered into complete germination as soon as the third day. Permitting then a small portion of air to enter the receiver where the seeds had not sprouted, we saw, in both cases, germination produced in two or three days.

In other experiments we have placed seeds in the act of sprouting in pure nitrous oxide; the development was arrested, and again resumed when a portion of air was allowed to enter the receiver. We have proved further that in protoxide of nitrogen plants do not exhale carbonic acid.

From these different experiments we believe that we may conclude that the oxygen of the protoxide of nitrogen cannot be utilized by plants for respiration; and if the contrary has been asserted, it is because the gas experimented upon, not being perfectly pure, contained a small quantity of oxygen, and we know that a very small quantity of oxygen only is needed for the commencement of germination.

Animals.—Frogs were placed, for comparison, in receivers containing respectively pure protoxide of nitrogen, carbonic acid, carbonic oxide, hydrogen, and nitrogen. While those plunged in hydrogen, nitrogen, and carbonic oxide only expired after two or three hours' stay in these gases, exhibiting at the termination stupor and drowsiness (as Jean Müller had already proved), those placed in carbonic acid were seized at once, and died quickly. The frogs placed in the nitrous oxide succumbed at the end of two hours' exposure to the gas.

We placed a sparrow under a jar containing 2.5 litres of protoxide of nitrogen, where death took place at the end of thirty seconds. One placed—for comparison—in a jar containing hydrogen, died in the same time.

A guinea-pig inspiring pure nitrous oxide by the trachea died in 2½ minutes.

In the same way a rabbit died suddenly at the end of

2 minutes and 24 seconds of respiration of pure nitrous oxide.

From these experiments, and others which we will not here recall, we are compelled to say that chemically-pure protoxide of nitrogen cannot support respiration in animals or plants. We may, therefore, here repeat the remark made above, that if certain authors have believed themselves able to demonstrate that this gas is one which can support respiration, it is because they experimented with impure nitrous oxide, containing a quantity more or less great of oxygen, according to the time more or less long that the animals lived in the gaseous compound.

b. Does the protoxide of nitrogen possess any specific properties?

If pure nitrous oxide is not able to support respiration in plants and animals, is it a gas inert, like hydrogen or nitrogen? or, on the contrary, being very soluble (water dissolving four-fifths of its volume), will it enter into the circulation by the way of absorption, and, dissolving in a greater or larger amount of blood, be carried to the nervous centres, there to produce peculiar effects, stupor, anæsthesia, etc.?

With this in view, we have studied the phenomena presented when animals are made to breathe pure nitrous oxide, or an artificial atmosphere of pure protoxide of nitrogen and oxygen.

Frogs placed in pure protoxide of nitrogen exhibit the following phenomena: After three or four minutes, more or less marked diminution in the respiratory movements of the throat and sides, soon followed by stupor and drowsiness, from which he rouses himself at intervals more or less prolonged. The animal spontaneously or following excitation makes a few respirations, and if placed on his back regains his natural position, and soon resumes his former stupor. In this condition the frog remains perfectly sensible to pinching of his toes, sensibility which can be proved after the expiration of forty-five minutes in the gas.

A guinea-pig was made to breathe, by the trachea, from a bag containing eight litres of pure nitrous oxide; thirty-five seconds after, the animal was perfectly sensible to pinching of his paws; after forty-five seconds respiration was labored, but sensibility remained intact. On allowing the animal to breathe air freely, he revived in a few seconds.

Half an hour later the same animal was again made to breathe the pure nitrous oxide. After one minute and forty-five seconds, sensibility was still preserved; after two minutes and twenty seconds, it was extinguished; and death supervened in two minutes and thirty seconds from the time the experiment was commenced.

A rabbit was made to respire pure protoxide of nitrogen. After one minute and forty-five seconds the animal struggled and showed signs of asphyxia, but sensibility was proved to persist. On withdrawing the nitrous oxide and allowing him to breathe the air, the animal rapidly recovered.

In another experiment upon a rabbit, sensibility existed even after two minutes and twenty-four seconds; at this moment respiration terminated abruptly, but we were able to restore the animal to life after some moments of artificial respiration.

The preceding experiments show that pure protoxide of nitrogen produces asphyxia with all its signs. Having noticed that anæsthesia occurred at the moment the animal's arterial blood became black (and knowing that, when animals are subjected to asphyxia, anæsthesia takes place as soon as the arterial blood only contains two to three per cent. of oxygen), in order not to attribute to nitrous oxide the concomitant anæsthesia, which may be attributed to pure and simple asphyxia, we have made the following experiments.

We added protoxide of nitrogen and oxygen in different proportions, so that the mixed gases contained eighteen to twenty-one per cent. of oxygen and sixty to eighty per cent. of nitrous oxide. In this way the animal had at his disposal a quantity of oxygen almost equal to that existing in atmospheric air, while at the same time the combination was sufficiently rich in nitrous oxide to produce its specific effects, if it really possessed any.

Frogs remaining twenty-four hours in a mixture of four-fifths protoxide of nitrogen and one-fifth oxygen did not present a single appreciable phenomenon; sensibility, when the toes were pinched, was very evident.

Two other frogs, after remaining five days in a receiver containing 300 cubic centimetres of oxygen to sixty per cent. and one litre of pure nitrous oxide, did not show at the end of this time either stupefaction or anæsthesia.

At twenty minutes past five o'clock we placed two sparrows, for comparison—the one under a bell-jar containing air, the other under a similar jar containing oxygen and nitrous oxide in the proportion of the gases of the atmosphere.

7 o'clock.—There was some trouble in respiration, noticed equally in both birds.

7.30.—We left the sparrows panting, puffed out, and both alike.

9 o'clock.—We found the birds dead.

On making an analysis of the air remaining in the jars, we found in the one containing air—

Carbonic acid . . . . . 11 per cent.
Oxygen . . . . . 6 "

In the one containing nitrous oxide and oxygen—

Carbonic acid . . . . . 12 per cent.
Oxygen . . . . . 5.8 "

At 2.40 P.M. we put a sparrow into a mixture of four litres of nitrous oxide and 600 cubic centimetres of oxygen. At 3.30 P.M. the same; no change in the appearance of the bird.

4 P.M.—He commenced to pant. We then collected the gas in the jar, which gave 9.2 per cent. of carbonic acid on analysis. The bird rapidly recovered.

At 6.45 P.M. we placed a sparrow under a two-litre receiver, containing oxygen and nitrous oxide in the proportion of 18 to 82 per cent. The bird remained quiet until 7.45 P.M., when his respiration became labored. When seen at 9 P.M. he was panting, and death took place at 9.15 P.M. The analysis of the gas in the jar gave 12 per cent. of carbonic acid and 3 per cent. of oxygen.

A small dog was made to breathe a mixture of protoxide of nitrogen and oxygen in the proportions of atmospheric air. By means of a caoutchouc muzzle and the valves of Müller, he only inspired the gas contained in the bag, the expirations going outside, so that there could be no complication from asphyxia by the carbonic acid. The animal breathed this mixture for twenty-two minutes, during all of which time he remained sensible without stupor or drowsiness; galvanization of his sciatic nerve by a feeble current produced pain, and, when he was called, he gave signs of attention.

These experiments show therefore that animals are able to breathe an artificial atmosphere containing eighteen to twenty per cent. of oxygen and sixty to eighty per cent. of nitrous oxide during a time sufficiently long, without showing any manifest phenomena, and, above all, without exhibiting anæsthesia.

As the protoxide of nitrogen is very soluble in water, which dissolves four-fifths of its volume, it was of interest to discover what quantity of it was in solution in the blood of those animals which breathed the artificial atmosphere and nevertheless showed no diminished sensibility, for comparison with that in the blood of animals breathing pure nitrous oxide, taken at the moment anæsthesia appeared, in order to decide what share in

this phenomenon to attribute to the nitrous oxide. It is also equally important to determine the quantity of oxygen existing in the blood at the same moment.

But we will first show rapidly the method of analysis of the gases of the blood which we have employed and have used also in the analysis of the mixed gases composed of oxygen, nitrous oxide, and nitrogen.

We have adopted the following, which M. Gréhant kindly pointed out for us:

The mixture to be analyzed, composed of oxygen, protoxide of nitrogen, and nitrogen, is introduced into the eudiometer.

Let v = the volume of the mixed gases, x = the oxygen, y = the nitrous oxide, and z = the nitrogen; then we have—

$$x+y+z=v.$$

By introducing a quantity of hydrogen b, we have in the eudiometer $v+b$. Now, if a spark be passed through this, the remainder may be expressed by r, and the amount lost will equal $v+b-r$.

But x of oxygen combines with $2x$ of hydrogen to form water, making a loss equal to $3x$; y of the nitrous oxide contains $\frac{1}{2}y$ of oxygen, which combines with y of hydrogen to form water, but gives y of nitrogen,* only y of hydrogen disappearing; we have then—

$$v+b-r=3x+y.$$

We add to r a volume d of oxygen, and there is in the receiver a volume $r+d$; on passing the spark there remains r'; $r+d-r'$ is the second volume disappearing, of which $\frac{2}{3}$ are hydrogen, which we will call e.

Having introduced a volume b of hydrogen, then $b-e$ = the hydrogen used in the first combustion. But x of oxygen required $2x$ of hydrogen, and y of the protoxide of nitrogen used y of hydrogen; therefore,

$$b-e=2x+y.$$

It remains to resolve these three equations with three unknown quantities:

$$\begin{aligned} x+y+z &= v. \\ 3x+y &= v+b-r. \\ 2x+y &= b-e. \end{aligned}$$

From which the values of x, y, and z are easily determined.

This said, we will relate some experiments, with the analysis of the gases of the blood determined in the preceding manner.

A dog breathing the surrounding air through the valves of Müller had in 100 cubic centimetres of arterial blood—

Carbonic acid	48.8 per cent.
Oxygen	21 "
Nitrogen	2 "

He was then made to breathe from a bag containing a gaseous mixture of 62 per cent. of nitrous oxide, 21 per cent. of oxygen, and 17 per cent. of nitrogen. The animal took seven minutes and thirty seconds to inspire fifty litres of this mixture; and during all this time his eye remained sensitive, and he took notice when his toes were pinched. The analysis of the gases of the blood, made then, gave for each 100 cubic centimetres of red arterial blood—

Carbonic acid	46 per cent.
Oxygen	19.7 "
Nitrous oxide	29 "
Nitrogen	0.3 "

The same animal, having rested half an hour, was made to breathe pure nitrous oxide gas for one minute and forty-five seconds; he was then much troubled in his breathing, but still remained sensible. On making then an analysis of the dark arterial blood, we found—

Carbonic acid	37 per cent.
Oxygen	5.2 "
Nitrous oxide	28.1 "
Nitrogen	0.7 "

A second dog, breathing, in the manner already explained, from a bag of nitrous oxide, was found to be insensible at the eye and to pinching after three minutes. The analysis of the gases of the blood, then made, gave for each 100 cubic centimetres of very dark arterial blood—

Carbonic acid	36.6 per cent.
Oxygen	3.3 "
Nitrous oxide	34.6 "

A third dog, breathing the nitrous oxide from a bag, was still somewhat sensible at the third minute; was found completely insensible to the electrization of the sciatic nerve after four minutes. Analysis of the black arterial blood then gave—

Carbonic acid	34 per cent.
Oxygen	0.05 "
Nitrous oxide	37 "

We might here relate other experiments, but think that these will be sufficient to enable us to draw the following conclusions:

When there is, in the arterial blood of dogs that breathe an artificial atmosphere of protoxide of nitrogen and oxygen, almost the same quantity of nitrous oxide in solution as that found in the same animals breathing, until asphyxiated, pure protoxide of nitrogen, we cannot attribute the anæsthesia which then appears to the presence of the nitrous oxide in the arterial blood. The cause of the anæsthesia is naturally found to be the result of the asphyxia, from the privation, more or less complete, of oxygen from the arterial blood. We know, in short, that when there is no more than two or three per cent. of oxygen in the arterial blood, anæsthesia commences to appear. (P. Bert.)

We conclude our article with the following propositions:

The protoxide of nitrogen, chemically pure, is not able to sustain respiration in animals any more than in plants; the combustion in which respiration consists not being sufficiently energetic to decompose the nitrous oxide gas.

Breathed pure, by animals, the protoxide of nitrogen is an asphyxiating gas, which produces death, with all the usual signs of asphyxia by strangulation or by respiration of the inert gases (nitrogen and hydrogen), and in almost the same time.

Breathed pure, if the nitrous oxide produces anæsthesia, it is by privation of oxygen from the blood; insensibility showing itself when the arterial blood commences to have only from two to three per cent. of oxygen. The arterial blood is then very black, and contains thirty to forty per cent. of protoxide of nitrogen.

Animals are able to live by breathing an atmosphere of protoxide of nitrogen and oxygen in the proportion of the gases in the air, the nitrous oxide replacing the nitrogen, without producing troubles of sensibility. The arterial blood then contains thirty to thirty-five per cent. of protoxide of nitrogen. Birds plunged in a similar confined atmosphere behave like those placed under a bell-jar of the same capacity containing air, and die after having nearly equally consumed the oxygen in the receivers, and formed as much carbonic acid.

The protoxide of nitrogen being an irrespirable gas, and possessing none of the anæsthetic properties that have been attributed to it, its employment can only be dangerous, and should be, under that title, proscribed from medical practice.

* [According to Bloxam, when NO is decomposed it gains half a volume; two volumes of NO containing two volumes of N, and one of O.—Tr.]

OBSERVATION UPON A CASE OF MIXED CHANCRE AND BUBO.

By Dr. P. Diday, of Lyons. Translated from *Annales de Dermatologie et de Syphiligraphie*, No. 5, 1873,

BY LOUIS A. DUHRING, M.D.

A YOUNG man, 25 years of age, came to consult me on the 8th of January, 1872. He told me his story, as follows:

"I have a mistress, to whom I had always been faithful. On the 30th of December, 1871, for the first time in my life, I went to a public house. The 3d of January, 1872 (that is to say, four days after), I perceived a small sore upon the penis."

I examined the patient, and recognized, upon the right side of the duplicature of the prepuce, an ulcer, presenting all the characters of the chancroid or non-infecting chancre, already well developed in size and general features. I prescribed a dressing of charpie soaked in a solution of nitrate of silver.

At the expiration of two weeks the patient returned to show me a painful swelling in the right groin. I diagnosed a commencing acute adenitis. The chancroid, which had been dressed very regularly, was already upon the way to recovery. The adenitis followed its fatally progressive course. Upon the 4th of February it was in a fluctuating condition, and I opened it, when several days later this opening presented a chancroidal aspect. As a dressing, I employed here the solution of nitrate of silver. At the end of about a month both the ganglionic and integumentary chancroids were healed. More than a month now elapsed, and I had entirely lost sight of the patient, when, upon the 10th of April, he returned, requesting me to give him my advice upon an eruption which annoyed him. I saw, indeed, a general roseola, some crusts upon the scalp, three glands enlarged on the back and high up on the neck, and some scales upon the palms of the hands. These symptoms, which were accompanied by pains in the head and stiffness of the neck, dated from about the 23d of March. The inguinal bubo had cicatrized. Under the integument of this region, which was still red, a ganglionic enlargement of small size, but of firm consistence, was perceptible. There was a less marked enlargement of two ganglia in the left groin, which were indolent.

In a former communication to the Medical Society of Lyons upon a wholly analogous case, I described the generation and evolution of these mixed affections, which, from the chancroidal origin about the penis and groin, afterwards assume, at that point, the aspect of the primitive lesions of syphilis and are followed in regular succession by the general symptoms peculiar to this disease. Above all, I insisted upon the causes of error that the association of these two distinct diseases can engender, and upon the consequences of these errors, fatal both to physician and patient.

To-day, studying another side of the subject, I will examine it in accordance with the doctrines, or rather the doctrine, which, it appears to me, the Faculty of Lyons have been too anxious to bury in oblivion. It is not, however, that I wish to dispute the certificate of death, quite *en règle*, which the Ecole de l'Antiquaille gave against it. But, nevertheless, I hear that the unity theory still lives somewhere in the heart of Austria, Bohemia, or elsewhere. We must then notice it here, if even for the last time. Now, what case, in appearance, was there ever more favorable to the old doctrine of the identity of the chancre-poisons than that of which you have just heard the recital?

"What!" the Austrian says to me, "what! you, Monsieur Diday, a dualist, *you* report the history of a simple chancre, of a chancroid? *you* describe it as a chancroid, but you only give it the *name* of a chancroid?

"To complete the picture; it engenders a chancroidal adenitis, and when the secondary symptoms break out later, you change your position by saying that, without doubt, it was a case of mixed chancre. But what observation can remain firm upon such a statement? Do you think that it is sufficient to *suppose* the existence of an infecting chancre, when it is too late to prove it, to convince us that it really did exist?

"The mixed chancre (*le chancre mulet*), we know, can stand a good deal, but by overstraining it do we not run the risk of running it into the ground?

"Even for their own good and preservation, ought not the dualists to connive at least at this one case?

'Have they no pity upon their old servant?'"

To this valiant attack, gentlemen, I have but one word to say. As with many practitioners, I remember that upon that day I was very much occupied, perhaps a little absent-minded, and, relying upon the existence of the chancroidal adenitis as establishing the diagnosis of the primitive ulcer, I neglected, upon the *third visit* of my patient, to look at the side of the penis (of which he did not complain) and to feel the base of the ulcer and assure myself whether or not this base presented any induration.

But even in the absence of this information I can affirm not only that an infecting chancre existed there, but, further, that it developed itself upon the chancroid or upon its cicatrix, about twenty-five or thirty days after its commencement.

Let us refer, in order to prove it, to that which we know concerning the evolution of syphilis. As a rule, especially when, as in the present case, no specific treatment intervenes, the secondary symptoms manifest themselves about six weeks after the commencement of the chancre. Now, in our patient the secondary symptoms were not manifested until eighty days after the beginning of the ulcer upon the penis. This ulcer then, which at its first appearance I recognized as being chancroidal, and nothing but chancroidal, is not the antecedent of these secondary symptoms. For, to borrow from medical jurisprudence one of its most expressive decisions, the symptoms first appeared too long after it to entitle it to be considered as the infecting source. The one source alone from which these symptoms can proceed is the other,—the *infecting ulcer*,—which I confess not to have looked for, but whose existence and paternity are clearly proven to me by the age of its offspring.

New Mode of Administering Cod-Liver Oil.—Numerous attempts have been made to render cod-liver oil less disagreeable, either by gelatinizing or solidifying it, but only with partial success. The system of capsules seems to answer best; but the great objection is the number of these which must be swallowed. Now it would seem that Messrs. Carre and Lemoine have contrived to incorporate the oil with *bread*. Each pound of bread contains a little more than two ounces of the oil, or five tablespoonfuls, and three ounces of milk. Small loaves are also made which contain only two tablespoonfuls, and which, altogether, weigh only five ounces. These loaves are beautifully white, look extremely well, and have hardly any taste. Both children and adults eat them very willingly. In M. Bouchut's ward, at the Children's Hospital in Paris, thirty-four small loaves are brought every morning, and are looked forward to with much anxiety by the children for breakfast. They have been largely used among private patients, and no one complains of any disagreeable taste. Five or six tablespoonfuls of oil may thus be given per diem, incorporated with the bread taken with the usual food.—*Lancet*, Aug. 2, 1873.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 27, 1873.

EDITORIAL.

TYPHOID FEVER IN LONDON.

VERY recently an alarming outbreak of typhoid fever has taken place in London, spreading through certain districts with great rapidity, and involving four or five hundred people.

It happened that several cases occurred in the household of Dr. Murchison, lately in charge of the Fever Hospital, and famous the world over for his work on continued fever. Feeling confidence in the sanitary arrangements of his dwelling, he was led to suspect some extramural cause, and instituted inquiries among several of his medical friends in the neighborhood, in whose families there were cases of typhoid fever. He found that in every instance the milk-supply, which he already regarded as the possible source of infection, was the same as that of his own household. He at once communicated with the medical officer of the parish; the milk company were summoned to suspend the sale of milk from their dairy, and a commission of inquiry appointed. It was found that of the eight farms with which the company contracted for the supply of milk, seven presented no probability of enteric contamination, but that to the eighth the most suspicious circumstances attached. The farmer, a strong middle-aged man, believed by his medical attendant to be suffering from a "fatty heart," was taken ill with indefinite symptoms about the second week in May. A fortnight later a consulting physician declared his case to be one of typhoid fever. His opinion was, however, disregarded, and the man was allowed to remain out of bed and walk about whenever he felt able to do so. For the first few days in June he had a copious diarrhœa with putrid and bloody discharges; this was followed by constipation, for which a dose of castor oil was given.

On June 8, as he was being lifted from his bed, he died. On account of the suddenness of his death, the doubt about the original diagnosis, and the fact that he seemed to have recovered from his recent illness, his medical attendant entered as the cause of death "heart-disease;" but fatal collapse is certainly of not unfrequent occurrence in typhoid fever, and the circumstance rather confirms than discredits that diagnosis.

The only privy on the premises was at the upper part of the yard, the bottom of its pit being two or three feet above the level of the well from which drinking-water was obtained, and the ground affording opportunity for free drainage.

At the time of the investigation the son of the farmer had just been taken sick with typhoid fever. It was also found that there had been an epidemic of the same disease in some neighboring villages. Acting upon these facts, the supply of milk from this farm was at once cut off by the proprietors, and since then the number of fresh cases of enteric fever breaking out in the west of London has greatly diminished. Of course much mischief has already been done, many lives have been sacrificed, and the seeds of the disease have been scattered broadcast, perhaps to originate new centres of infection; but it is due to the sagacity of Dr. Murchison in the first instance, and to the energy, courage, and ability subsequently displayed by the official investigators, that the evil has not been greater and the mischief much more extended. The cotemporary from whom we gather these interesting and important facts remarks that the occurrence of the epidemic has given a remarkable stimulus to the investigation of the media of infection of the typhoid-poison, and, it is to be hoped, with important results.

SINCE the above editorial was in type, the *British Medical Journal* of September 6 has been received, and contains much new information in regard to the present epidemic and the conveyance of enteric and other fever poisons in milk. It seems that the milk company, being a corporation, and therefore soulless, objected very strongly to their business being interrupted, asking for proof that the typhoid-

fever poison was in the milk, although they had been assured that out of thirty-seven families stricken with the fever thirty-five were supplied with their milk. They wanted, forsooth, this mysterious entity,—the typh-poison,—this thing that eye hath not seen, precipitated from their milk, weighed, analyzed, and delivered in sealed packages at their office, so that they might put it into the hands of a chemist to have its identity proven!

Even the medical health officer of the parish tried to interfere, but to no avail; and finally the sale of the poison was only checked after some days of discussion, when apparently public opinion and the fear of future damages to be judicially awarded induced this most worthy body corporate to investigate the matter.

The following extract from a letter of Dr. Murchison will show the evidence relied on by him and Dr. Jenner as demonstrating the origin of the disease:

"Out of sixty families [placed under the same conditions as to drainage, etc., as their neighbors] of the better class, already known to us, in which enteric fever has appeared within the last month, all but one have used your milk.

"In certain families not supplied by your company, individuals have been attacked with enteric fever who have accidentally partaken of your milk, and then these individuals have been the only members of the family who have suffered.

"An unusually large proportion of the patients have been young children who consume much milk. In certain families, children who drank water, but not milk from your dairy, have remained exempt; while the children who drank Dairy Reform milk have suffered; and of the adults who have taken the fever, most have been milk-drinkers."

Meanwhile, the epidemic has given rise to a great deal of discussion in regard to the production of contagious disease by milk. A Dr. Michael Taylor, of Penrith, has written a most excellent letter to a daily journal, in which he takes the ground, apparently the true one, that the contagion always gets into the milk after it has left the body of the cow. It is well known that milk is a powerful absorbent, readily acquiring the odor and taste of substances with which it is in proximity, and it appears just as ready to appropriate bad as good,—contagion as perfume. The letter of Dr. Taylor is so to the point, and the subject so important, that we quote a part of his words at length:

"It is," he says, "fifteen years ago since I brought before the profession the facts and arguments in support of my discovery of typhoid poisoning by the milk-supply. The whole story was told at the time in the *Edinburgh Medical Journal*, 1858. The facts were derived from an investigation of an epidemic in this town, similar in essential particulars to that now prevailing in Mayfair. The cows were healthy; the use of sewage grass or hay was unattainable; the addition of foul water to the milk, either by accident or by design, was practically impossible, the only available supply being the public service of pure water from Ullswater. The fever-virus entered the milk in this wise. The cows were milked by the hands of a woman who was nursing cases of typhoid fever on the premises; the milk-cans were brought into the room in which the sick were lying, and remained there until sent away to the customers. It was during the process of milking, while the thin warm stream was flowing, or whilst standing exposed to this atmosphere of fever-miasms, that the warm freshly-drawn fluid absorbed the fever-virus, and afterwards communicated the disease to those who drank it. In the outbursts of typhoid fever which exploded along the track of a milk-walk at Leeds in 1872, as reported by Dr. Robinson, and again in Glasgow in 1873, as reported by Dr. Russell, the explanation of the manner in which the milk became infected is the same as I have indicated above.

"There have been frequent outbreaks of enteric fever in Penrith arising from sewage stagnation, owing to the ignorance or supineness of the local sanitary authorities, but not again implicating a dairy until the year 1867, when a death from scarlatina occurred in a milkman's cottage. A rapid and fatal outburst of the pest among the families of the customers ensued, and an investigation forced the conviction that again the milk was the vehicle of the poison, and that the old dormant observations of 1858 were receiving their first corroboration. And it were well at the present time to be mindful that milk is a potent vehicle for the dissemination of this frequent and mortal zymotic scourge, scarlatina, and it may be of cholera also. Up to this time three distinct epidemics of scarlatina have been proved to have been diffused by milk, and have been publicly reported—viz., 1, that in Penrith in 1867, by Dr. Taylor himself; 2, in St. Andrew's in 1870, by Dr. Oswald Bell; 3, in Leeds in 1872, by Dr. Robinson. In the reports, they all agree as to the mode in which the poison was introduced into the milk. The cows were milked by scarlatina convalescents, or by those engaged in nursing the sick. In this disease the dry epidermic dust, the *débris* from the peeling skin, was the carrier of the infective germs. From the arms and dress of the milker it was shaken into the milk-pail, or absorbed by the milk from an atmosphere charged with these floating particles. In these instances it was not a question of a malady in the cow, nor of the use of sewage-grass, nor of the admixture of impure water. The evidence all bore on the direct mingling of the exuviæ, or infective germs (if science can yet honestly admit such as a known quantity), proceeding directly from the bodies of the sick or from the absorption by the milk of the fever-exhalations from the vitiated atmosphere in the vicinity of the sick."

IT is a matter which we think needs discussion, why, with our almost universal private cesspools, we are so exempt from epidemics of typhoid fever in Philadelphia. The disease is always with us, but anything like a spreading epidemic is a thing unheard of, at least in our experience.

Again, it is very difficult to understand the relations between the two forms of the disease. Are they really one? or is our "typhoid fever" a duplex entity? On the one hand there is a disease, most frequent, arising hourly in our great centres, but spontaneously and without obvious cause, never spreading, never in any tangible way connected with the entrance of a poison into the blood. On the other hand there is an affection occurring in wide-spread or local epidemics, apparently as contagious as scarlet fever, apparently as dependent upon the entrance of a poison into the system as smallpox. Won't some of our readers explain this matter for us?

WE notice that Dr. E. G. Janeway has been elected Professor of Pathological Anatomy, Professor of Practical Anatomy, Lecturer on Clinical Medicine, and Lecturer on Materia Medica and Therapeutics, in Bellevue Hospital Medical College. Verily the sun of professorial grandeur blazes upon our distinguished friend. We are reminded of the gentleman whom the genial Mark Twain met in the Wilderness. "Think of hotel-keeper, postmaster, blacksmith, major, constable, city-marshal, and principal citizen, all condensed into one person and crammed into one skin. Bemis said he was a perfect 'Allen's revolver of dignities.'" We wish joy and success to our "concentrated" professor.

We also learn that Dr. Hammond has resigned his various positions in connection with the same school. New York, and especially Bellevue, seems in the last year or two to have been afflicted with an epidemic of resignations. The constitutions of the Philadelphia Faculties are, we greatly fear, so strong as to resist any contagion. It is said an epidemic leaves a city in a more vigorous condition.

THE Berlin medical journals record the death from cholera, on August 20, of Dr. Otto Obermeier. Dr. Obermeier was already known to science by his investigations of disease. Within the last few months he had published some interesting researches on the blood in typhus fever (maculated), and, when seized with his fatal illness, was engaged in researches on cholera. Emboldened by his not having contracted the fever during his exposure, he somewhat recklessly kept in his bedroom pathological specimens taken from persons who had died of cholera, and also portions of their excreta; and, according to one account, even injected some blood from cholera patients into his own vessels. He was so devoted to his inquiry that, after he had become aware of the condition in which he was, he made some microscopic examinations on his own blood. His death occurred after an illness of seven hours, in the thirty-first year of his age.

M. GUBLER demonstrated to the Société Thérapeutique of Paris, at the séance of August 13, 1873, the fact that senna will cause a discoloration of the urine precisely similar in appearance to that which occurs in jaundice. On the addition of nitric acid, however, to the urine, the biliary reaction does not occur; moreover, caustic potash changes the color to a magnificent purple. Caustic potash added to the infusion of senna produces only a faint indication of purple, and it is probable that the principle of senna undergoes an oxidation in the system similar to that of turpentine, asparagus, etc.

IN a paper read before the British Medical Association, Dr. H. MacCormack advocates the use of anæsthetics to deprive animals of consciousness previous to slaughtering. As meat so treated would taste of ether or chloroform, we suppose all our palates would have to be educated before it would be agreeable. In another paper by the same author, read under the same auspices, it was shown that, by resort to a tube with artificial nipple properly adjusted, goat's milk might be abstracted from the living animal and transferred at once to the infant's stomach.

M. E. ROUX, in a recent communication to the French Academy (*Gazette Médicale de Paris*, August 23), asserts, as the results of experiments upon himself, that tea, and still more coffee, increases the elimination of urea. The exercise and diet being the same, the following table expresses the results:

	Daily elimination of urea.
From 14th to 18th of May (without coffee or tea)	36.18
18th of May (coffee)	41.05
From 16th to 18th of June (without coffee or tea)	33.76
18th of June (tea)	37.04

UP to the 15th of August there had been this season three hundred deaths from cholera at Vienna.

IN another column we give the translation of a French article upon nitrous oxide. The authors' science may be true; it may be that giving nitrous oxide is only a neat way of producing partial asphyxia; but certainly their practical deductions are simple nonsense. It is only the old story of Mrs. Partington and the broom.

LATE dispatches announced that the illness of M. Nélaton had taken a favorable turn, and he was supposed to be convalescent; but on Saturday last he suffered a relapse, sank rapidly, and died the same night, in the seventy-sixth year of his age.

REVIEWS AND BOOK NOTICES.

A Treatise on the Pneumatic Aspiration of Morbid Fluids. By Dr. Georges Dieulafoy. J. B. Lippincott & Co., Philadelphia, 1873.

Great practical discoveries in the art or science of medicine, revolutionizing practice, extending wider the control of the physician over disease, are, unfortunately, most rare. If the instrument, or rather principle, which Dr. Dieulafoy has been so fortunate as to discover, should fulfil the promise of the present, it will be, at least to our thinking, one of the most useful additions to our knowledge since the days of Laennec,—not affecting, indeed, so wide a range of cases as does auscultation and percussion, not comparable to the work of the great physician named, in its laborious science, but, like it, rendering, though in a more limited sphere, a hitherto obscure—nay, impossible—diagnosis certain, and, unlike it, adding a new therapeusis capable of rescuing from death cases hitherto beyond our art. The idea of penetrating closed cavities by means of hollow needles did not, as every one knows, originate with Dr. Dieulafoy; but the principle which shall render his name so famous is what he calls the "previous vacuum." By means of finely-made workmanship, a cylinder is exhausted of its air; from the end of the cylinder projects a nozzle closed by a stop-cock, and to the nozzle is attached a long, hollow, sharp needle of varying size, according to the object in view. This needle is then plunged into the tissue above the cavity to be evacuated, and when its point has entered the flesh for the distance of half an inch the stop-cock is opened, so that the needle to its point partakes of the vacuum of the cylinder. It is evident that so soon as the needle, on being pushed forward, enters fluid, the latter will be seen to spurt up into the glass cylinder; and it is equally evident that by means of a readily-contrived apparatus allowing of the conversion of the aspirator, when nearly full, into a siphon, any cavity in the body may be emptied.

The application of such an instrument as this to the purposes of diagnosis and of therapeusis is at once very plain, provided the use of it be harmless. The great power of the previous vacuum allows of the employment of a very fine needle, provided that the slender bore is kept free from dirt and rust, precisely as in hypodermic syringes; and experience has demonstrated that these needles may be plunged anywhere into the body without injury, unless it be into the heart itself. Indeed, as Dr. Dieulafoy and his followers have practised aspiration hundreds of times in inflammation of the knee without affecting the joint, except for good; as in retention of urine the bladder has been punctured ninety-eight times without a single accident; as in strangulated hernia numerous aspirations have been made without irritating in the least the intestines; as both the healthy and the diseased liver have been traversed in every direction, without harm, and the pericardium has been tapped with the best results,—it seems to us that no one can read the volume recording these successes without being convinced of the harmlessness of aspiration.

The diseases in which the process has been especially practised are hydatids and abscess of the liver, retention of urine from organic causes, hydrocephalus, spina bifida, strangulated hernia, various serous inflammations, synovitis of the large joints, and abscesses.

In a number of cases of hydatids of the liver, and in a single one of hepatic abscess, the results obtained have been most encouraging. A curious phenomenon noticed in several cases is the sudden development of urticaria with nausea and vomiting directly after the puncture. The cause of these is mysterious, but the symptoms are evidently of nervous origin, and have subsided without doing harm.

Dr. Dieulafoy details a very remarkable case of poisoning in an infant six hours old, by a dessertspoonful of laudanum. In this, aspiration and injection of the stomach was performed a dozen times in the course of ten minutes, and the viscus so thoroughly washed out that the child recovered. Dr. Rasmussen, of Copenhagen, gives the details of a case of spina bifida in which he effected a cure by means of aspiration.

We pass by the chapters on the use of aspiration in strangulated hernia, merely stating that the harmlessness and apparently the efficiency of the procedure are such that it should always be applied previous to the last efforts at taxis.

Space also fails us to follow our author through the many pages devoted to consideration of the application of his method to pleuritis, peritonitis, pericarditis, synovitis, etc. The subject of aspiration is one of such grave importance that it behooves every man who practises medicine or surgery not to be content with such information as can be conveyed in the limits of even the longest review, but to read the book carefully, to ponder its teachings, and to test its methods conscientiously at the bedside.

From a literary point of view, the book of Dr. Dieulafoy is fairly good; marred, however, by an offensive egotism,—an incapability of its author to forget for a moment that it was *I* who did this thing. We make no objection whatever to a man claiming even pertinaciously a discovery or invention he has made; we detest the mock modesty, the prudery, which so often betokens and is the offspring of an over-sensitive egotism, that causes an author, in total disregard of English grammar, to "we" himself; but we cannot with complaisance witness a rain of I's upon the pages of a book,—comparable only to an Egyptian plague of frogs.

In conclusion, the mechanical execution of the work is excellent. Indeed, the book is evidently not American to the manor born, but a naturalized citizen, claiming the paternity of a famous race, though born on British soil.

Lectures on Clinical Medicine. By A. Trousseau. Translated from the Third Revised and Enlarged Edition by Sir John Rose Cormack, M.D., and P. Victor Bazire, M.D. Complete in two volumes. Lindsay & Blakiston.

To criticise or review Trousseau's Clinical Medicine would be as novel in its performance and in its results as to speak forth platitudes on the comprehensiveness of Shakspeare or the dignity of Milton. Our readers—all of them, we trust—know as well as ourselves the merits and demerits of this great work; the monument

of a master-mind, it has been seen and read of all men.

The only matter of interest is as to the guise in which our old friend appears anew.

The volumes, then, before us are simply an American reprint of the Sydenham Society's edition, with the notes by Bazire omitted,—a popular edition of a medical classic,—cheap, but not altogether nasty,—holding the same relation to its British progenitor that an American book generally does to an English one. As the price is only ten dollars, as each volume is composed of nearly one thousand extra-large closely-printed pages, as the matter is most excellent, whoever buys this work gets the worth of his money,—a consummation devoutly to be prayed for.

Believing that in these few lines we have given our readers just the information they desire, we will not encroach further upon their time and patience.

GLEANINGS FROM OUR EXCHANGES.

Court Plaster.—A writer in the *Journal of Pharmacy* gives the following details. The difficulty in making a court plaster in most cases is generally that of cracking and breaking, which the addition of glycerin prevents. The following formula produces a superior quality of court plaster, that will not crack or break:

℞ Russia isinglass, ℥j;
Water, Oj;
Alcohol, f℥j;
Glycerin, ℥ss.

Soak the isinglass in the water for one day, then dissolve it by the aid of a gentle heat, after which strain it and add the alcohol and glycerin. The mixture, being now ready for use, is spread on a fine quality of silk stretched on a frame, each successive coat being allowed to dry before applying the next. Heat should not be used in drying the plaster, as it is apt to drive the glycerin out and leave the plaster streaked.

By another formula, court plaster is made in the following manner:

℞ Russia isinglass, ℥iss;
Resin, ℥xiv;
Alcohol,
Water, āā q. s.;
Glycerin, f℥ss.

Beat the resin in a mortar until perfectly powdered, then dissolve it in alcohol q. s., and mix with the isinglass solution; strain and add the glycerin.

Court plaster made in this way is very adhesive, but not as handsome as when made by the previous formula.

In another formula, gelatin is used instead of isinglass, and makes a very handsome plaster.

℞ Gelatin, ℥iss;
Water, Oj;
Glycerin, f℥j.

Soak the gelatin in the water for one day, then dissolve it by the aid of a gentle heat, and after it is dissolved add the glycerin.

This mixture, if spread on coarse and heavy silk, makes a white and opaque plaster; while if spread on thin and finer silk, the plaster will be nearly transparent and of a yellowish tint.

Case of Cephalic Chancroidal Ulceration.—Dr. R. W. Taylor, of New York, in the *Archives of Scientific and Practical Medicine*, records a case of chancroidal ulceration occurring upon the forehead of a man, just above the eyebrow. The patient, the subject of numerous chancroids about the penis, while ascending a ladder carrying a hod upon his shoulder, stumbled and struck his forehead violently against one of the rungs. The wound bled freely, and received but little care.

Four days after this accident, an undoubted chancroidal ulceration was observed at the seat of the injury upon the forehead. To verify the diagnosis, an inoculation with some of the pus from the ulceration was made upon the abdomen of the patient, which was then carefully protected. Four days after, a small undermined ulcer was present. The chancroidal ulcer of the forehead was treated with fuming nitric acid, and ran the usual course of a chancroid. Undoubtedly reliable reported cases of chancroidal inoculations about the head are rare. Dr. Taylor quotes the histories of four cases, and considers his as the fifth authentic case on record.

The Psychology of the Toad (by Dr. Thomas Hill, of Portland).—This paper consisted of half a dozen anecdotes of instances of intelligence and docility in the toad which had come under Dr. Hill's observation, and which he wished to put on record as a slight contribution towards the comparative psychology of batrachians. The most striking anecdote was that of a toad which had swallowed one end of a large earthworm, and had become so tired in its attempts to get the rest down that it was in danger of losing the whole, the worm crawling out of the toad's mouth faster than it could be swallowed. The toad then brought up its right hind foot, and, grasping its stomach and the worm in it, held the worm in with its foot, taking a fresh grip after every gulp, until the job was finished.—*Proc. of the Am. Assoc. for the Adv. of Science.—N. Y. Tribune.*

Curability of Pulmonary Phthisis.—An article published by Dr. R. Massini, of Basle, in *Deutsch. Arch. für Klin. Med.* (H. 3 and 4, 1873), contains the following remarks on the above subject, the results of the author's personal experience: In pulmonary phthisis two-thirds of the fatal cases belong to cheesy pneumonia, and in only one-third of the cases is tubercle to be found. It is impossible in our present state of knowledge to assert that miliary tubercle is curable. It is shown by the results of post-mortem examinations (discovery of cicatrices in the apices of the lungs) that cheesy pneumonia, when not complicated by tubercle, can be cured. Pulmonary phthisis, adds Dr. Massini, is frequently a consequence of abdominal typhus, and at Basle the mortality from phthisis has considerably diminished since the decrease of cases of abdominal typhus.—*London Lancet*, Aug. 23, 1873.

A Pharmaceutical Curiosity.—The Berlin correspondent of the *Chemist and Druggist* sends the following specimen of extraordinary pharmacy, culled from the first edition of the Prussian Pharmacopœia (*Dispensatorium Borusso-Brandenburgicum*, 1731). This is in Latin. The specimen which he selects is "Spiritus Cerebri Humani," p. 206 (Spirit of Human Brain). "The brain of a young man, well built and perfectly healthy, but who has been put to death by some violent means, must be crushed, with all vasculars and the spinal marrow, in a stone mortar; afterwards mixed in a glass retort, or in a large phial, with 'Kaiser Karls Hauptwasser' (somewhat similar to our eau de Cologne) and spirit of wine. This mixture is to be distilled after having stood by for one, or, better, for several years. The dose of this elegant remedy was fixed at a tablespoonful."

The death of M. Mériadec Laennec, a relative of the illustrious discoverer of auscultation, and himself an author of some note, is announced to have taken place lately.

NINE CASES OF COLOTOMY (by Christopher Heath, F.R.C.S.).—The nine cases related all occurred in females. Two operations were undertaken for cancer of the rectum, causing obstruction, which had existed many days; both patients died. Three operations were performed for scirrhus in an earlier stage, before obstruction had occurred; and of these one died and two recovered,—one of the latter dying seven months afterwards, and the other being now alive and well, seven months after the operation. Two operations were performed for syphilitic ulceration and stricture; both recovered, and are alive now. One operation was performed, as a last resource, in a patient worn out with extensive fistula and ulceration (probably syphilitic) before she applied for relief, and proved fatal. The operation was performed for the relief of a recto-vesical fistula, and was perfectly successful. The result therefrom was four deaths and five immediate recoveries. Mr. Heath appended some observations on the operation and its results, urging its earlier adoption in cases of obstruction and intractable disease, and showing the slight risk to the patient the operation *per se* inflicted. In the discussion which followed, Messrs. Maunder, Parsons (Liverpool), Meade (Bradford), Humphreys (Shrewsbury), and the president, approved of the operation. Messrs. Heath (Newcastle) and Maunder preferred the transverse incision; the latter made the wound conical, with the apex towards the deeper parts. He had met with enormous quantities of subperitoneal fat obstructing the operation. Dr. Parsons (Liverpool) had a successful case of infantile colotomy; the patient, now twenty years old, working as a dock-laborer.—*Transactions British Association, British Med. Journal*, Aug. 30.

HOW TO MAKE LIEBIG'S SOUP FOR BABIES.—The value of this soup, prepared according to Liebig's directions, is not fully appreciated in this neighborhood, partly, perhaps, because it is not often tried, and partly, no doubt, because it is supposed to be the same thing as the so-called Liebig's Food which is put up in tins by Savory and Moore. It may be that there is some way of preparing Savory and Moore's powder so as to make it palatable and digestible. But, although H.R.H. Prince Albert Victor throve on it well (vide advertisements), it must be confessed that, prepared according to the directions given, it is not very palatable, and, as far as my experience goes, not particularly digestible. The receipt for Liebig's soup is given in several books in English, but entirely without the details of the process, so that one only finds out how to prepare it well and quickly after a good many experiments. I feel sure, however, that, if the detailed directions which I give below are strictly followed, the soup will be made without difficulty.

(A.) One measure of malt, mixed with one measure of solution of bicarbonate of potash, should be left to stand half an hour.

Malt, ready ground, may be obtained of beer-brewers, though they do not make a business of selling it; it may well be sifted through a coarse sieve, to remove the largest hulls. It is well to buy bicarbonate of potash in half-ounce packages, and dissolve one package at a time in one quart of water. A large wineglass, or small teacup, answers conveniently for a measure.

(B.) Make a porridge of one measure of flour in five measures of milk.

To avoid lumps, mix a part of the milk with the flour first, and make it perfectly smooth before adding the rest of the milk. The flour should be of as coarse a quality as can be obtained.

It is not very easy to boil the porridge enough to swell the starch thoroughly and yet not burn the mixture. The most convenient vessel is a milk- or farina-boiler; though any two vessels of such sizes that one will make a water bath for the other will answer the purpose. It is easier to swell the starch thoroughly by having but little water in the water-bath and depending on the steam for heating, than by having so much water in the bath that the smaller vessel will dip into it. If there be a fire of hot coals at hand, it is well to make sure that the porridge is thoroughly boiled, by taking the vessel which contains it out of the bath and letting it stand on a toasting-rack over the hot coals, but not touching them. It is less likely to burn in this way than if put on the iron surface of a range or stove.

(C.) Let both the water-bath and the porridge cool down to about 140° or 150°, add the malt and potash slowly while stirring, and let it stand at the above temperature fifteen or twenty minutes, when it becomes thin and sweet.

When the porridge has been thoroughly boiled, it is best to fill up the water-bath, so that an even temperature can be maintained. It is certainly possible to get along pretty well without a thermometer, remembering 150° is very hot, but not boiling. Many failures, however, will be prevented by using a thermometer, which can be prepared easily from one of the ordinary, cheap thermometers which are used in dwelling-houses, by drawing it out, together with the metal scale, from the black frame, and cutting off so much of the scale with strong scissors that the glass part only will dip into the porridge. If the soup does not now become thin and sweet after standing fifteen or twenty minutes, some mistake has been made.

(D.) Boil it up once and strain it through a sieve and then through muslin.

If it were not boiled up this last time it would sour readily, but, when boiled, it keeps twenty-four hours perfectly well.

(E.) Dilute it with an equal quantity of water for a young child, and gradually increase the strength till the child is eight months old, when it may be taken in full strength.

It should be diluted only just before using, and kept in a perfectly cool place.—*Boston Medical and Surgical Journal.*

THE EVILS OF HIGH-HEELED SHOES.—Dr. Von Rothmund, Sr. (Munich), writes us as follows:—

Who would gather violets must not be frightened by the pricking of the thorns; and if one has the courage to cast a lance he must not be frightened off by the women. I do not propose in this paper to distress the reader with a dissertation on the follies of female fashion, but I shall venture to call attention to a few points in connection therewith, and I commence now at the bottom. I have nothing to say, then, about corsets, upon which folios have already been written, but I have a few facts to bring forward about the clothing of the feet. The high heels lately introduced into fashion change the long axis of the body, so that the trunk is directed backwards, and this of course alters the inclination of the pelvis. Such an alteration cannot be without influence upon conception and labor. I leave it to the obstetricians and gynæcologists to collect observations upon these facts. In my own experience I can bring forward one evil resulting from this *bizarre* position of the foot, viz., displacement forwards, even dislocation of the ankle-joint. I had a case under treatment where a dislocation occurred as a result of the predisposition thereto by high-heeled shoes, and where the patient was confined to bed for three months, notwithstanding the best treatment that could be devised. Inflammation of the ligaments and the sheaths of the ligaments is much more frequently met with. Finally, an abundance of corns is a product of this shoe dress that is not to be overlooked. Indeed, the corn-doctors are the only ones

benefited by this refinement of luxury.—*Wien. Med. Presse*, June 15, 1873.—*Boston Medical and Surgical Journal.*

A Mode of using a Three-pad Tourniquet in the Treatment of Aneurism (by E. Lund, F.R.C.S., Manchester).—The tourniquet employed was that known as Signoroni's, with a pad from the centre of the arch, so attached that it could be moved to and fro by a screw-action. The instrument was applied in the usual way over the artery, and such pressure made as would not arrest entirely the force of the pulsations. The extra pad was then brought into action, so as to press against the external side of the limb and drag the tourniquet transversely across it. This had the effect of so displacing the vessel and the tissues surrounding it that the artery was made to assume a curvilinear in place of a straight direction; and by this means the circulation could be completely stopped with less actual compression of the skin and other structures.—*Transactions British Association, British Medical Journal*, Aug. 30.

On a New Method of determining the Presence of, and Recovery from, True Ringworm (by Dyce Duckworth, M.D.).—The author called attention to the action of chloroform upon the infected hairs in cases of tinea tonsurans. It was shown that this agent caused the hairs to become white or slightly yellow in color, and thus to be distinctly mapped out and easily distinguishable from surrounding healthy hairs. The causes of the change were briefly discussed, and the particular phases of the disorder suitable for this application were pointed out. The effect of chloroform on patches of favus, tinea versicolor, melasma, and alopecia areata was likewise discussed. It was shown that no other reagent, so far as was known, possessed the peculiar properties of chloroform in affecting parasitically diseased hairs.—*Transactions British Association, British Medical Journal*, Aug. 30.

Subcutaneous Injections.—Dr. Constantin Paul recommends glycerin as a dissolvent for subcutaneous injections. He considers it to be far superior to water, alcohol, etc.; it is neutral, can be kept easily, and is, of all liquids, the one which approaches the nearest to the composition of subcutaneous cellular tissue.—*Lancet*, Aug. 2, 1873.

Third Attack of Measles.—I have a young lady, about twenty-three years of age, suffering for the *third* time from an attack of measles! All the characteristic symptoms, such as the eruption, the deeply-congested state of the mucous membranes of the eyes, nose, larynx, and bronchia, are most pronounced.—*Charles Anderton, in London Lancet*, July 26, 1873.

At the meeting of the Société de Biologie, July 5, 1873, M. Rabuteau called attention to the purgative effects of the hypersulphites of soda and magnesia, which he had found to be extremely satisfactory, but their use could not be advised, owing to their high price and their disagreeable taste.—*Le Progrès Médicale*, July 12.

Liquid Nourishment for Sick Stomach.—An egg, well beaten up, to which add one pint of good milk, one pint of cold water, and salt to make it palatable; let it then be boiled, and when cold any quantity of it may be taken. If it turns into curds and whey it is useless.—*H. S. Halahan, in Dublin Medical Journal.*

Dr. T. Bates proposes (*The Clinic*) to substitute meal for bran in fracture-dressings as an absorbent. The meal, he claims, is equal to the other dressing, and is much superior in that it packs better and holds the limb immovable in the apparatus.

MISCELLANY.

The "Brunetti process" for the preservation of the dead consists of several processes. 1. The circulatory system is cleansed by washing with cold water till it issues quite clear from the body. This may occupy from two to five hours.

2. Alcohol is injected, so as to abstract as much water as possible. This occupies about a quarter of an hour.

3. Ether is then injected, to abstract the fatty matters. This occupies from two to ten hours.

4. A strong solution of tannin is then injected. This occupies for imbibition two to ten hours.

5. The body is then dried in a current of warm air passed over heated chloride of calcium. This may occupy two to five hours. The body is thus perfectly preserved, and resists decay. The Italians exhibit specimens which are as hard as stone, retain the shape perfectly, and are equal to the best wax models.—*Ed. J. Hallock, in Journal of Applied Chemistry.*

Rusticus writes in the *Boston Medical and Surgical Journal* as follows: "Please say to the other country doctors, who don't know any more than we do, that pepsin can be very easily made an 'Aromatic Liquid Pepsin' by cutting up a calf's rennet-bag and bottling it up in half a gallon of pale sherry. It won't cost nearly so much; and mother used to feed her thirteen babies on it, at the rate of a teaspoonful to a cup of milk, with a little sugar mixed in, and a scratch of nutmeg on the top.

"I am told that you can buy rennet-bags cheap in Boston market. They are much better, I believe, after drying for weeks; and I should prefer them to pepsin. They will keep longer and better."

Boylston Medical Prizes.—At the meeting for 1873 of the Boylston Medical Committee, prizes of one hundred and fifty dollars each were awarded to David T. Lincoln, M.D., of Boston, for a dissertation on "Electro-Therapeutics," and to William C. Dabney, M.D., of Charlottesville, Virginia, for a dissertation on "The Value of Chemistry to the Medical Practitioner."

The following are the questions proposed for 1874:

1. The best method of preventing the development and spread of smallpox.

2. The development and extension of malignant disease.

Dissertations on the above subjects must be transmitted to J. B. S. Jackson, M.D., Boston, on or before the first Wednesday in April, 1874.

The expenses to the London profession of entertaining the British Medical Association were £1050, including £500 for three days' luncheons, more than £200 for the printing of circulars, the museum catalogue, programmes, etc., and £125 for charges connected with the public dinner, guests, etc.

At the last sitting of the Paris Academy of Medicine, Professor Hirtz, formerly of the Faculty of Strasburg, was elected a member.

THE QUESTION OF THE CO-EDUCATION OF THE SEXES IN GERMANY.—The Cologne *Gazette* has an article on the education and employment of women in Germany, called forth by the demand of the Russian female students to be permitted to study at German universities, which gives some new facts and lucidly illustrates the present drift of German thought. The faculty at Heidelberg University has, it will be remembered, distinctly declined to admit women to the classes. The *Gazette* says:

"The more general admission of women to the postal, telegraph, and railway services is the plain German answer to the demand made by the Russian students to be permitted to study at German high schools. It is very satisfactory to find that at all German universities where the question has been discussed, mostly in consequence of applications made by the Russian female students, the university authorities have decided against the admission of women. It is surely no degradation of the sex that men refuse to receive women at public educational institutions which by their nature are destined for men; the success of female students of medicine and law is moreover, setting aside a few brilliant exceptions, very doubtful, and as there were only two or three German female students of medicine at Swiss universities who can continue their studies there, there seems to be no reason why Germany should alter her whole university system simply because the Russian girls want to study.

"The increased employment of educated women in the public and private service is a very different matter. If the state sets the example, there can be no doubt that private railway companies will follow, and employ women on duties which they can perform as well as men and at less wages. The more general employment of women in different bureaus of the administration will also show on what other duties women are fit to be employed. That it is necessary to look to this is illustrated by the statistical tables published, which show that emigration and other causes have increased the number of unmarried women enormously. Other states, for instance Switzerland, France, and England, are in advance of Germany on this question. The increased admission of women to the Imperial postal and telegraph service is the consequence of a demand made in the last session of Parliament after a lively debate, in which the well-known deputy Leewe appeared as the advocate of women."

A FRENCH prefect wrote to one of the mayors of his department, advising him, as the cholera had broken out in the district, to take all the necessary precautions. After some time the mayor wrote to say that he had taken all the proper steps; and upon the prefect sending to see that they were effectual, he found that the only preparation the mayor had made consisted in having a large number of graves dug in the churchyard.

THE Erie Railroad Company have appointed a regular medical bureau in connection with their road, whose past history shows that such provision was badly needed.

A TRIBUTE TO THE DOCTORS.—Mr. Gladstone was a guest at the recent dinner of the British Medical Association. In acknowledging the compliment of a toast to "Her Majesty's Ministers," Mr. Gladstone paid a high, but not undeserved, tribute to the medical profession. He said that but for the care and watchfulness of a succession of able physicians it would have been impossible for him to have gone through the fatigues of political life. "It is," he proceeded, "among the mournful and noble distinctions of your illustrious profession that, although its members may not receive that acknowledgment which awaits the soldier when he falls on the battle-field, yet they are to be found in countless numbers among the truest martyrs in the cause of humanity." He complimented the practitioners of the medical art on their high claims to consideration for their promotion of beneficial sanitary legislation. He said that medical knowledge has advanced in recent years in a degree which is not, perhaps, paralleled in any other profession. There is at the present day "a greater and more sustained earnestness of purpose, and a more general exaltation of the aims of medical men."

Mr. Gladstone said in conclusion, "This age is distinguished by an unbounded activity in all the sciences of observation. Of all those sciences yours is the noblest. It is given to you to study the relations between the wonderful body and the still more wonderful soul and mind of man. You tread that border-land in which the two come in contact. It is very easy to describe the post-office or the railway system, but you have to deal with a thing far more subtle when you attempt to grasp human nature as a whole. Human progress is not to be described by formularies. It is only by the most patient observation that a sound and comprehensive knowledge on such a subject can be acquired. To you it belongs to seize the great opportunities and to accept the great responsibilities which attach to the profession of which you are members, and to show yourselves worthy of the great vocation with which you are intrusted."

THE following is from Dr. Parvin's address before the Medical Editors' Association:

"As Robert Southey well says in 'The Doctor,' man is a dupable animal. Quacks in medicine, quacks in religion, quacks in politics, know this, and act upon the knowledge. There is scarcely any one who may not, like a trout, be taken by tickling. A church dignitary once said, '*Populus vult decipi; et decipietur.*'"

COST OF CONDUCTING A MEDICAL JOURNAL.—The following are a few items in round numbers of the expense incurred in conducting the *British Medical Journal* the past year: editor $1560, sub-editor $500, printer $24,250, contributions $4800, stationery $1400, sundries $3000.

WE are glad to learn that it is intended to devote a portion of the immense wealth of the late eccentric Duke of Brunswick towards founding a faculty of medicine at Geneva.
